Abstract: The objective of the current study was to provide more appropriate therapeutic strategies for reducing severe hemorrhaging by assessing the recovery of abnormal coagulation indexes in patients with acute promyelocytic leukemia (APL) during induction therapy. Retrospective analyses of 112 patients newly diagnosed with APL were performed during initial treatment. In our study, the early death rate was 5.36%. Hemorrhage was the leading cause of death during the induction period (4/6). The values of white blood cell count, lactate dehydrogenase, prothrombin time (PT), fibrinogen (Fbg), hemoglobin, and bone marrow leukemic promyelocytes were significantly different in the high-risk group compared to the low/intermediate-risk groups. There were significant differences in the white blood cell count, bone marrow leukemic promyelocytes, platelet (PLT) count, and the levels of lactate dehydrogenase, D-dimer, PT, and Fbg, as well as in FLT3-ITD mutations between patients with major bleeding and those with minor bleeding. Hemostatic variables significantly improved over time during induction therapy. The recovery times of the PLT, PT, and Fbg values were significantly slower in patients with major bleeding than in those with minor bleeding. Specifically, the PLT level in patients with major bleeding was not similar to that in the minor bleeding group until after 4 weeks of treatment. Hemorrhages were the most common cause of induction death in this study. High-risk patients were more prone to serious clinical bleeding symptoms. Patients with major bleeding had more rapid proliferation characteristics and an increased incidence of FLT3-ITD mutations compared to patients with minor bleeding. Hemostatic variables recovered significantly more slowly in patients with major bleeding than in those with minor bleeding. Active induction therapy and blood product infusion are effective in preventing severe bleeding. Our results suggested that low PLT count might be the leading cause of fatal bleeding in patients newly diagnosed with APL.

Keywords: acute promyelocytic leukemia, all-trans retinoic acid, arsenic trioxide, coagulation, hemorrhage

Introduction

Acute promyelocytic leukemia (APL) is identified by the predominance of abnormal promyelocytes in the bone marrow (BM) and a specific chromosomal translocation – t(15;17) – resulting in a fusion transcript between the promyelocytic (*PML*) gene on chromosome 15 and the retinoic acid receptor alpha (*RARα*) gene on chromosome 17; this transcript is known as PML–*RARα*.¹ The t(15;17) chromosomal translocation can induce hyperexpression of tissue factor (TF) in cells of patients with APL and render the patient hypercoagulable.² All-trans retinoic acid (ATRA) and arsenic trioxide (ATO) are the current cornerstones of APL therapy, and these treatments have dramatically

improved patient outcomes. ATRA improves the terminal differentiation of leukemic promyelocytes in patients with APL, and ATRA-induced remission is associated with an improvement in the coagulopathy of these patients.³ ATO also promotes the molecular remission of APL and addresses the associated coagulopathy by reducing membrane procoagulant activity (PCA) and TF expression.^{4,5} Despite this tremendous progress, APL still remains associated with a high incidence of premature death due to the frequent occurrence of abrupt bleeding diathesis. The presence of coagulopathy is an important risk factor for early hemorrhagic death in APL patients.⁶ Changes in clinical and laboratory parameters before and during induction therapy were examined in this study to identify more appropriate therapeutic strategies in order to reduce hemorrhage-mediated mortality.

Patients and ethics statement

A total of 112 patients newly diagnosed with APL were treated at Jiangsu Province Hospital, The First Affiliated Hospital of Nanjing Medical University (Nanjing, People's Republic of China), between May 2009 and April 2016. This cohort included 66 males and 46 females with a median age of 41 years (range: 12–75). The APL diagnostic criteria were based on the World Health Organization Classification of Tumors–Pathology and Genetics of Tumors of Hematopoietic and Lymphoid Tissues (2008) and French–American–British classification systems (1976) criteria.⁷ A molecular diagnosis was confirmed by identification of t(15;17) in a cytogenetic analysis and/or positive detection of PML–RAR α using either fluorescence in situ hybridization or reverse transcription-polymerase chain reaction. The immune phenotype diagnosis of APL was established by positivity for CD33, CD9, CD13, and CD117, and low expression of HLA-DR and CD34. Early death (ED) was defined as death due to any cause within 30 days of diagnosis. Other inclusion criteria were as follows: no severe liver disease (abnormal liver function, alanine aminotransferase/aspartate aminotransferase greater than 2.5 times the normal value, or total bilirubin greater than 1.5 times the normal value), no cardiovascular disorders or other hemorrhagic diseases, and no usage of anticoagulants during induction therapy. We collected data from May 2009 to April 2016 and identified the diagnostic information during and after data collection. The study was approved by the ethics committee at Jiangsu Province Hospital, affiliated with Nanjing Medical University. Written informed consent was obtained from all the enrolled subjects, including legal guardians on behalf of the minors recruited in our study.

Treatment strategies

The treatment followed the Shanghai APL protocol with some minor adjustments during the introduction period.⁸ Daily administration of intravenous ATO (10 mg/day) was started immediately when APL was suspected, and oral ATRA (25 mg/m²/d) was then prescribed upon genetic confirmation until the patient achieved complete remission (CR) after induction therapy. Additional chemotherapy (idarubicin 8 mg/m²/d for 3–4 days or daunorubicin 45 mg/m²/d for 3–4 days) was administered to control hyperleukocytosis if the peripheral white blood cell (WBC) count was greater than 10 \times 10⁹/L or on the second day in high-risk patients (pretreatment WBC count >10 \times 10⁹/L).

In addition to systemic treatment, patients were given central nervous system prophylaxis via six intrathecal injections of 10 mg of methotrexate, 50 mg of cytosine arabinoside, and 5 mg of dexamethasone. Therapeutic platelets (PLTs), fresh frozen plasma (FFP), or cryoprecipitate was transfused when clinically relevant bleeding occurred. A prophylactic PLT transfusion strategy (when available) was administered when the PLT count was lower than 50 \times 10⁹/L. Patients received only random ABO identical (non-HLA-typed) apheresis PLTs for PLT transfusions. In China, one apheresis unit is standardized to contain at least 2.5 \times 10¹¹ PLTs with less than 5 \times 10⁸ leukocytes. Prophylactic transfusion of either FFP or cryoprecipitate was mainly based on fibrinogen (Fbg) levels lower than 1.5 g/L. One unit of cryoprecipitate was converted into 200 mL of plasma for the subsequent statistical analysis.

Laboratory studies and clinical outcomes

The obtained information included demographic (age, gender), clinical (initial bleeding events and early hemorrhagic death events), and laboratory variables (WBC count, hemoglobin [HB] levels, PLT count, prothrombin time [PT], activated partial thromboplastin time [APTT], Fbg, D-dimer, lactate dehydrogenase [LDH], FLT3-ITD transcript type, and bone marrow leukemic promyelocyte [BMP] percentage). Routine blood tests were performed using a Sysmex XT-4000i Hematology Analyzer (Sysmex, Kobe, Japan) on EDTA-anticoagulated blood samples. The Sysmex CS-2000i Automated Hemostasis Analyzer (Sysmex) was used to detect coagulation and fibrinolysis parameters such as the PT, APTT, and Fbg levels (Clauss method) and D-dimer (immuno-turbidimetric method). Biochemical blood tests were done on a Beckman Coulter AU5800 Biochemical Analyzer (Beckman Coulter, Brea, CA, USA) using heparin-anticoagulated blood samples.

Blast counts and promyelocyte percentages were determined by microscopic examination of the BM by two experienced physicians separately. Fusion gene transcripts from chromosomal aberrations were analyzed by reverse transcription-polymerase chain reaction. FLT3-ITD mutations and the PML-RAR α gene fusion were detected in BM samples collected at the time of APL diagnosis.

Statistical analysis

The prognostic risk stratification of APL is based on a widely recognized risk evaluation standard that originated from the Italian GIMEMA and the Spanish PETHEMA trials:²⁶ low risk, WBC $\leq 10 \times 10^9/L$ and PLT $> 40 \times 10^9/L$; intermediate risk, WBC $\leq 10 \times 10^9/L$ and PLT $\leq 40 \times 10^9/L$; and high risk, WBC $> 10 \times 10^9/L$.¹ The outline of bleeding scores in idiopathic immune thrombocytopenia in China is based on the immune thrombocytopenia-specific bleeding assessment tool.⁹ Bleeding manifestations were classified (with gradations of severity) based on age and three major domains: skin, visible mucosae, and deep organs. Severity was scored from 1 to either 3 or 5, with a score of 8 assigned for any fatal bleeding (Table 1). We classified ≥ 6 as major bleeding and < 6 as minor bleeding. Statistical analysis was conducted using SPSS software 16.0 (SPSS Inc., Chicago, IL, USA). The results are presented as the mean \pm standard deviation for normally distributed data and as the median for nonnormally distributed data. Comparisons were made using Student's *t*-test, Fisher's exact test, and analysis of variance. *P*-values less than 0.05 indicated statistical significance.

Results

In our study, 112 patients were newly diagnosed with APL based on morphology and detection of the PML-RAR α mutation and/or t(15;17)(q22;q21). Sixty-six of the 112 evaluated patients (58.93%) were male and 46 (41.07%)

were female (ratio: 1.43:1). The median age at diagnosis was 41 years (range: 12–75 years). Among the entire cohort, 22 patients (19.64%) were classified as low risk, 63 (56.25%) were intermediate risk, and 27 (24.11%) were high risk. The patient characteristics are summarized in Table 2. The ED rate in our study was 5.36% (6/112). Among these six deaths, five were extremely early (< 7 days of induction). The causes of ED in these 5 cases were intracranial hemorrhage (3), pulmonary hemorrhage (1), and acute renal failure (1). One of the patients with intracranial bleeding also had concomitant pulmonary hemorrhage. The sixth patient died of severe infection, and he also suffered from type 2 diabetes with poor glycemic control. All the patients who survived past 1 week achieved remission. Thus, the CR rate was 95.53% (107/112). Hemorrhagic events account for the majority (66.67%) of the EDs.

We analyzed the clinical characteristics of all 112 patients. The median age of the cohort was 43 years (range: 12–75 years). Stratification of APL risk according to the Sanz stratification, which is based on WBC and PLT counts, remains the most reliable and valid method for rapidly identifying high-risk APL patients. We divided the patients into two groups: 85 (75.89%) were low/intermediate risk, and 27 (24.11%) were high risk. Among the 27 high-risk patients, 18 were male, and 9 were female; there was no statistically significant difference in the gender distribution of the two risk groups (low/intermediate group: 48 males and 37 females, $P=0.455$). The median age of the high-risk patients was 43.19 years versus 40.32 years for the low/intermediate-risk patients ($P=0.383$). The WBC count at presentation was higher in the high-risk group (median: $38.30 \times 10^9/L$) than in the low/intermediate-risk group (median: $2.62 \times 10^9/L$, $P=0.000$). The average Fbg concentration was lower in high-risk patients than in low/intermediate-risk patients (0.90 ± 0.51 vs 1.48 ± 0.85 ; $P=0.000$).

Table 2 Baseline laboratory parameters in the APL cases

Laboratory parameters	Values
Age (years), median (range)	41 (12–75)
Gender, male/female	66/46
WBC ($\times 10^9/L$), median (range)	11.22 (0.30–89.98)
HB (g/L), median (range)	86.03 (29–146)
PLT ($\times 10^9/L$), median (range)	33 (5–231)
LDH (U/L), median (range)	422.41 (121–3,571)
BMP (%), median (range)	82.62 (47.6–97.2)
CR rate (%)	95.53
ED rate (%)	5.36

Abbreviations: APL, acute promyelocytic leukemia; BMP, bone marrow leukemic promyelocytes; CR, complete remission; ED, early death; HB, hemoglobin; LDH, lactate dehydrogenase; PLT, platelet; WBC, white blood count.

The levels of HB, LDH, and BMP at presentation were higher in high-risk patients (median: 94.44 g/L, 847.26 U/L, and 85.81%, respectively) than in low/intermediate-risk patients (median: 81.61 g/L, 287.45 U/L, and 81.61%, respectively; $P=0.044$, $P=0.000$, and $P=0.038$, respectively). The PT value at presentation was higher in high-risk patients (median: 17.33 s) than in low/intermediate-risk patients (median: 13.77 s, $P=0.003$). However, the PLT, APTT, and D-dimer levels at presentation were not significantly different in high-risk patients compared to low/intermediate-risk patients (Table 3). The bleeding scores of high-risk patients were all ≥ 10 , and the percentage of low/intermediate-risk patients with severe bleeding (≥ 6) was 48.24% (41/85).

Then 6 cases of ED were excluded, and the remaining 106 cases (61 males and 45 females) were analyzed in the subsequent studies. We divided the 106 patients into the major bleeding and minor bleeding groups based on the bleeding rating scale. Among the 60 patients with major bleeding, 35 were male and 25 were female; there was no statistically significant

difference in the gender distribution of the two bleeding groups (minor bleeding: total 46, 26 males and 20 females, $P=0.852$). The median age of the patients who suffered from major bleeding was 40.77 years versus 41.15 years for those with minor bleeding ($P=0.893$). There was a significant difference in the number of WBCs ($17.90 \times 10^9/L$ vs $1.16 \times 10^9/L$, $P=0.000$) and PLTs ($25.72 \times 10^9/L$ vs $43.65 \times 10^9/L$, $P=0.011$) between the major bleeding group and the minor bleeding group. However, there was no significant difference in the mean HB level (86.62 g/L vs 85.54 g/L, $P=0.828$) or the APTT (26.36 s vs 26.79 s, $P=0.544$). There were significant differences in LDH (519.39 U/L vs 249.35 U/L, $P=0.002$), D-dimer (7.09 $\mu g/mL$ vs 13.23 $\mu g/mL$, $P=0.026$), PT (15.39 s vs 13.60 s, $P=0.004$), Fbg (1.09 g/L vs 1.66 g/L, $P=0.001$), and BMP (84.04% vs 80.18%, $P=0.033$) (Table 4).

We also analyzed the changes in the hemostatic variables in 106 patients during induction therapy. The recorded time points were the time of diagnosis, before initial treatment, and at 0.5, 1, 1.5, 2, and 4 weeks after initiating treatment with ATO + ATRA and/or chemotherapy. All the observed variables showed statistically significant differences that quickly changed over time. The PLT, PT, APTT, and Fbg values appeared to significantly improve at 0.5 weeks after initiating induction therapy, and the D-dimers began to decrease after 1 week of therapy. There were significant differences in the changes in PLT, PT, and Fbg ($P=0.005$, $P=0.018$, and $P=0.022$) between the major and minor bleeding groups after 4 weeks of introduction therapy, but there were no significant differences in the changes in APTT and D-dimer ($P=0.746$, $P=0.333$). Further comparisons showed that differences in the Fbg levels were present only at diagnosis ($P<0.001$), with no significant difference between

Abbreviations: APTT, activated partial thromboplastin time; BMP, bone marrow leukemic promyelocytes; D-D, D-dimer; Fbg, fibrinogen; HB, hemoglobin; LDH, lactate dehydrogenase; PLT, platelet; PT, prothrombin time; SD, standard deviation; WBC, white blood count.

the two groups after initiating therapy ($P_{0.5W}=0.053$, $P_{1W}=0.246$, $P_{1.5W}=0.160$, $P_{2W}=0.506$, $P_{4W}=0.510$). The PT differed between groups at 0 weeks ($P_{0W}=0.008$) and 0.5 weeks ($P_{0.5W}=0.019$), but there was no significant difference starting 1 week after initiating introduction therapy ($P_{1W}=0.563$, $P_{1.5W}=0.615$, $P_{2W}=0.857$, $P_{4W}=0.070$). However, differences in the PLT levels were present during the first 2 weeks ($P_{0W}=0.005$, $P_{0.5W}=0.009$, $P_{1W}=0.000$, $P_{1.5W}=0.047$, $P_{2W}=0.007$) but disappeared by the end of the fourth week of therapy ($P_{4W}=0.740$) (Figures 1–5).

Discussion

APL is a clinical and biological variant of acute myeloid leukemia that is characterized by a cytogenetic abnormality,

$t(15;17)(q22;q12)$; PML-RAR α .¹ APL has a good prognosis based on the high rates of CR and survival achieved with therapies containing ATRA and/or ATO. Unlike other subtypes of acute myeloid leukemia, the primary cause of treatment failure in patients with APL is ED, which is defined as death within the first 30 days of diagnosis. There are multiple causes of ED in patients with APL, although death during induction therapy is most frequently related to hemorrhagic diathesis due to hyperfibrinolysis, proteolysis, and disseminated intravascular coagulation, which is further complicated by thrombocytopenia.¹⁰ In this study, the overall ED rate was 5.36% (6/112). In comparison with developed countries, the mortality in the current study was within previously described ranges of 5%–10%.^{6,11–13} All the patients who

succumbed to ED had a low PLT count, with a mean PLT count of $24.33 \times 10^9/\text{L}$ at presentation. Hemorrhages have been reported to occur in 90% of APL patients.¹⁴ ED due to hemorrhage before and during induction therapy currently remains the main cause of treatment failure in APL.^{6,15} Hemorrhage is responsible for most cases of death during the induction period, and it accounted for 66.67% (4/6) of the EDs in this study. Furthermore, most hemorrhagic mortalities in this study were attributed to intracranial and pulmonary hemorrhages. All these fatal events occurred within the first week of hospitalization.

ED is particularly frequent among high-risk patients, and a high WBC count ($> 10 \times 10^9/\text{L}$) was suggested as an adverse prognostic factor for bleeding complications in APL.^{16,17}

Abbreviation: Fbg, fibrinogen.

Almost all patients had laboratory findings of intravascular coagulation, increased fibrinolysis, and decreased PLT production due to marrow invasion upon initial presentation. It is common for patients newly diagnosed with APL to present elevated D-dimer levels, fibrin split products, prolonged PT, and partial thromboplastin time and hypofibrinogenemia.¹⁴ These unusual indicators are related to the clinical manifestations of a high risk of bleeding and thrombosis. In addition to an elevated WBC count at presentation, high-risk patients with APL in our study also had high LDH, HB, and PT levels; increased BMP percentage; and low Fbg levels. Despite the rapid proliferation characteristics, high-risk patients had more abnormal coagulation variables. Based on bleeding score, all patients in the high-risk group had severe bleeding (score ≥ 10). There was no doubt that high-risk patients were more prone to severe bleeding.

Reported risk factors for severe hemorrhage include low initial Fbg levels, poor performance status, and high WBC count.¹⁸ We identified patients with major bleeding based on decreased values of Fbg, D-dimer, and PLT; high values of WBC, LDH, PT, and BMP; and positivity for FLT3-ITD. The repeated finding that total WBC count is an independent predictor of major bleeding complications is not surprising. Elevated BMP and LDH levels were also a reflection of excessive proliferation. The presence of coagulopathy and low PLT levels were associated with the development of hemorrhages. Low PLT counts are usually due to impaired PLT production and consumption. Increases in D-dimer and decreases in Fbg levels are evidence of hyperfibrinolysis.^{19,20} Notably, patients

with major bleeding had lower D-dimer levels compared to patients with minor bleeding; this finding might explain why none of the randomized data showed a benefit of the clinical application of antifibrinolytics, which could block primary hyperfibrinolysis. Some studies have suggested a possible correlation between FLT3-ITD and the occurrence of ED in APL patients.^{21,22} Patients with major bleeding had a significantly higher prevalence of the FLT3-ITD mutation in the current study. Our results suggested that the bleeding score, which is mainly based on the hemorrhage severity, was a good approach to distinguish APL patients with different clinical and laboratory characteristics. The establishment of a bleeding scale that is more consistent with the bleeding characteristics of APL has realistic clinical value.

Leukemic cells isolated from APL patients with the typical t(15;17) chromosomal balanced translocation exhibit high levels of PCA, including TF and cancer procoagulant, which are associated with the induction of hypercoagulability. ATRA induces cell differentiation of APL in vitro, which is associated with the loss of cancer procoagulant or TF expression. ATO, another effective agent for treating APL, also decreases TF expression and PCA in malignant APL cells both in vitro and in vivo.⁴ Therapy with ATRA and ATO leads to an improvement in the coagulopathy and a reduced risk of severe hemorrhage.²³ After implementing the aggressive induction regimen, the hemostatic variables were significantly restored within 0.5–1 week compared to the initial levels. This confirmed that rapid initiation of therapy is important for treating APL. The ATO + ATRA regimen could quickly relieve the coagulopathy burden during the induction period. Thus, if an APL diagnosis is suspected based upon cytologic criteria, the recommendation is to immediately start introduction therapy without delay – even before obtaining definitive genetic confirmation of the diagnosis.

After aggressive treatment, the recovery rates of PLT, PT, and Fbg levels were significantly slower in patients with major bleeding than in those with minor bleeding. In the major bleeding group, Fbg and PT levels increased to similar levels as those in the minor bleeding group after 0.5–1 week of induction therapy. Interestingly, the PLT levels in the major bleeding group were significantly lower than those in the minor bleeding group during the 2 weeks of induction therapy; this index was not similar in the two groups until after 4 weeks of treatment. Patients with major bleeding require aggressive prophylactic transfusions based on frequent complete blood count and clotting tests. Blood products consisting of PLT transfusions, FFP, and Fbg concentrate (typically cryoprecipitate) are the cornerstone

of prohemostatic treatments. Our findings suggested that sustained low PLT levels were the most important factor in major bleeding. Possible causes of sustained low PLT levels include malignant clonal proliferation (which reduces PLT production), PLT infusion resistance (which causes ineffective infusion), and chemotherapy-induced BM suppression. Clinicians should aim for higher PLT counts in patients with APL during induction therapy, which may help prevent death due to hemorrhage in these patients. Therefore, in addition to aggressive induction therapy and supportive care, a reduction in the use of chemotherapy should also be considered. Lo-Coco et al have shown the efficacy and safety of ATRA in combination with ATO in patients with low/intermediate-risk APL. However, the ATRA + ATO regimen alone may be inadequate for high-risk patients.^{24,25} New immunotherapies such as CD33 monoclonal antibodies may be a viable method for better reducing the incidence of severe bleeding in APL.

This study had some limitations, including small sample size, short follow-up period, and single-center, retrospective design. There is an urgent need for more randomized, prospective trials of different induction regimens and new drug applications.

In conclusion, fatal hemorrhage remains the main cause of ED during the induction period in patients newly diagnosed with APL. High-risk patients had severe coagulopathy and were more prone to serious bleeding. The establishment of a bleeding scale that is more consistent with the bleeding characteristics of APL may better distinguish APL patients with different clinical and laboratory characteristics. Rapid onset of introduction therapy with the ATO + ATRA regimen could relieve the coagulopathy burden of APL patients. Aggressive prophylactic transfusion is the cornerstone of prohemostatic treatments. Finally, this study suggested that sustained low PLT levels were the most important factor in predicting severe bleeding. A higher PLT count should be the goal for patients with APL during induction therapy, as it may help prevent hemorrhagic death in these patients.
