Objective: To determine if vitamin D deficiency was associated with higher odds of left ventricular dysfunction among patients with acute coronary syndrome (ACS) and, if so, to determine whether this association was mediated by increased inflammation as measured by C-reactive protein (CRP) and white blood cell count (WBC).

Methods: This was a cross-sectional study of 170 participants with ACS. Multiple logistic regression was used to examine the association between the outcome of ventricular performance and serum vitamin D concentrations. We also determined whether CRP and WBC meet standard criteria as the mediators between left ventricular ejection fraction and vitamin D deficiency.

Results: Participants with vitamin D deficiency were more likely to have ventricular dysfunction (OR: 2.12, 95% CI: 1.2–5.23). WBC counts did not meet one of the criteria for mediation. However, the WBC was an effect modifier such that the association of vitamin D deficiency and ventricular dysfunction was only present among participants with WBC more than 11,000.

Conclusion: This study found that vitamin D deficiency was associated with higher odds of ventricular dysfunction. Further longitudinal and experimental studies are necessary to confirm this finding and to determine if there is a role for vitamin D supplementation therapy in preventing ventricular dysfunction in select patient populations.

Keywords: ventricular dysfunction, vitamin D deficiency, acute coronary syndrome, ejection fraction

Introduction

25-Hydroxyvitamin D (25(OH)D) deficiency is a common public health problem throughout the world. The analysis of the National Health And Nutritional Examination Survey (NHANES) estimated that the prevalence of vitamin D deficiency among adult men in the United States was 40%. Moreover, it demonstrated an increasing trend of vitamin D deficiency among the entire population during 1990–2014.1

Acute coronary syndrome (ACS) refers to any signs or symptoms of coronary artery stenosis that includes unstable angina, non-ST segment elevation myocardial infarction (NSTEMI), and ST segment elevation myocardial infarction (STEMI). According to recent studies, there is a correlation between vitamin D concentrations and risk factors for coronary artery syndrome such as dyslipidemia, hypertension, obesity, diabetes mellitus, and inflammatory factors.2–5 In addition, 25(OH)D deficiency is common among patients with ACS and associated with increased risk of ACS complications.6 It has been suggested that left ventricular ejection fraction (LVEF), as a reliable indicator in ventricular...
dysfunction, has been affected more severely among patients with ACS who have low serum vitamin D concentration.

The pathogenesis of cardiovascular disease is not fully understood, but evidence suggests that inflammation, endothelial dysfunction, and platelet aggregation may contribute to the development of ACS. The anti-inflammatory effects of 25(OH)D have been considered over several decades. Recent studies determined that vitamin D and its analogs consistently suppress proinflammatory cytokines and increase anti-inflammatory markers in the bloodstream. Akbas et al reported the inflammatory regulation role of vitamin D in their study. They presented the ratio of neutrophils-to-lymphocytes and platelets-to-lymphocytes, as an inexpensive, universally available inflammatory markers. The result of their study revealed an inverse association between serum vitamin D and novel inflammatory markers.

Blood cytology is commonly applied to predict outcomes among patients with ACS. Anemia is associated with increased rate of hospital mortality. Leukocytosis is also linked to a significantly higher risk of heart failure, and mortality among patients with ACS. Thrombocytosis may cause dysregulation of coagulation, with an increased risk of severe complications. For this reason, one of the potential pharmacodynamic pathways for some medications like statin is control of the platelet aggregation response by activating vitamin D metabolites, which may lead to improvement in symptoms of ACS and could also reduce the risk of developing ventricular dysfunction.

Given that 25(OH)D deficiency induces endothelial damage by inflammatory dysregulation and platelet aggregation and, based on the absence of studies exploring the effect of vitamin D deficiency on inflammatory markers and its prognosis among patients with ACS, we aimed to determine whether 25(OH)D deficiency is associated with ventricular dysfunction among patients with ACS. Given some published evidence that vitamin D reduces the concentration of inflammatory markers in the blood, we evaluated the role of the white blood cell (WBC) count, and C-reactive protein (CRP) as the mediators in this study.

Materials and methods
This cross-sectional study was conducted at Seyedo Shohada teaching Hospital between May 2015 and June 2016 in Urmia, Iran.

Patients with a final diagnosis of unstable angina, ST segment elevation, and non-ST segment elevation MI were considered to have ACS in this study. Myocardial infarction (MI) is defined by two of the following criteria.

1) Symptoms/signs of myocardial infarction or unstable angina which are confirmed by cardiologist. 2) Electrocardiographic findings which are compatible with the diagnosis of myocardial infarction. 3) Biochemical markers of myocardial injury to establish myocardial damage (Creatine kinase-MB [CK-MB] or Cardiac troponin).

The project was reviewed and approved by the Urmia University of Medical Sciences Institutional Board. The Social Determinant of Health Research Center of Urmia Medical Sciences University also approved the study design. The aim of this study and possible harm were explained to each participant. Patients signed the consent form to confirm their awareness of all procedures.

Blood samples were obtained within the first few hours after admission and delivered to the reference laboratory. Serum 25(OH)D (ng/mL) concentration was quantified by electrochemiluminescence (ECL) using Cobas E44 analyzer.

According to the Institute Of Medicine expert committee (IOM), we defined 25(OH)D deficiency as a serum concentration of less than 10 ng/dL. Moreover, we categorized 25(OH)D concentration as a categorical variable defined as normal, insufficient, and deficient levels of vitamin D in this study. Patients with vitamin D concentrations between 10 and 20 ng/mL were defined as being of insufficient levels.

Demographic and behavioral characteristics including age, sex, settlement classification (rural/urban areas), smoking status (never, ex-smoker, and current smoker), and body mass index (<25, 25–30, and ≥30 kg/m²) were potential confounders.

Diabetes, hypertension, ST and non-ST segment elevation MI, the season of admission, leukocytosis, anemia, thrombocytosis, and CRP were other covariates in this study. Patients who had reported taking antidiabetic/antihypertensive agents for at least 6 months were considered as diabetic/hypertensive patients in this study.

Anemia was defined as a hemoglobin level of less than 12 mg/dL in women and less than 14 mg/dL in men. Positive CRP was defined as the CRP level ≥10 mg/dL.

The normal range of WBC was 4,500–11,000. Platelet count between 350,000 and 100,000 was considered as the normal level.

Left ventricular ejection fraction (LVEF) was the outcome variable. Echocardiography was performed for all patients by using two-dimensional echocardiography within 3–7 days of admission. Simpson, BAL estimation eye methods were used to measure LVEF. An ejection fraction of less than 45% was identified as left ventricular dysfunction.
Statistical analysis

Descriptive statistics were reported as mean (standard deviation) or median (interquartile range, IQR) for continuous variables, and as frequency (percentage) for categorical variables. For comparisons of patients with 25(OH)D deficiency versus those with normal concentration, chi-square tests were used to compare categorical variables. Student’s t-test and the Wilcoxon rank-sum test were used to compare continuous variables, as appropriate.

Multivariable logistic regression models were fit to explore the association between 25(OH)D concentration and ventricular dysfunction. The model was then adjusted for demographic characteristics (age, sex, and settlements classification) as potential confounder variables. Next, we adjusted for behavioral and other covariates (BMI, smoking, blood pressure, diabetes, leukocytosis, anemia, and CRP).

Furthermore, we determined whether the inflammatory markers, including CRP and WBC, met the standard criteria as mediators between 25(OH)D deficiency and patient prognosis, as measured by LVEF. Logistic regression analysis was conducted to evaluate the following hypotheses: 1) the inflammatory markers (CRP, WBC) are associated with 25(OH)D deficiency; 2) 25(OH)D is significantly associated with ventricular dysfunction; 3) the inflammatory markers are associated with ventricular dysfunction; and 4) the effect of 25(OH)D deficiency on the odds of developing ventricular dysfunction is attenuated when inflammatory markers are added to the model. It is necessary to reject the null of all four hypotheses to support CRP and WBC as mediator variables.

STATA version 13 was used for analysis. Statistical significance was defined using a two-sided P-value <0.05 for all analyses.

Results

Characteristics of study population

In total, 170 patients with an ACS diagnosis were included in the analysis. The mean age of the study population was 59.42±13.60 years. Participants were mostly male (69.41%) and from the urban areas (65.29%). The study population was mostly admitted in the winter and fall (74.1%). The prevalence of having non-ST segment elevation MI was 35.50%. Almost half of the patients with ACS had normal blood pressure. Approximately half had no history of smoking, compared to 36.47% who were current smokers. Seventy-eight percent of participants were CRP positive. Forty-seven percent of patients had leukocytosis. The prevalence of left ventricular dysfunction was 62.9%.

Comparison of participants with normal 25(OH)D concentrations and those with 25(OH)D deficiency

Eighty-four percent (142/170) of study population had low 25(OH)D concentrations. Table 1 compares the demographic characteristics between two groups. Participants with 25(OH)D deficiency were more likely to be younger (P=0.002), but were less likely to be male and smokers than those with normal 25(OH)D concentrations; however, the differences were not significant statistically. Anemia was more common among patients with 25(OH)D deficiency (68.2% vs 31.8%, P=0.02). Patients with 25(OH)D deficiency were more likely to have leukocytosis than those with normal 25(OH)D concentration (P=0.04). However, the two groups did not differ according to other demographic, clinical, and laboratory variables.

Association of 25(OH)D deficiency and left ventricular dysfunction

We examined the association of 25(OH)D deficiency and ventricular dysfunction using logistic regression analysis. As shown in Table 2, the first unadjusted model showed a higher odds of ventricular dysfunction associated with 25(OH)D deficiency (OR: 2.12, 95% confidence interval [CI]: 1.2–5.23). A similar result was found after adjusting for demographic and behavioral variables (age, sex, settlement classification, BMI, and smoking status). Further adjustment for clinical and laboratory characteristics (hypertension, diabetes, anemia, leukocytosis, type of MI, etc.) did not meaningfully change the association (Table 2).

Subsequently, logistic regression analysis was used to determine the association between 25(OH)D concentrations as a categorical variable (normal, insufficient, or deficient) and ventricular dysfunction. Patients with 25(OH)D insufficiency were less likely to have ventricular dysfunction even after adjustment for demographic and clinical variables, compared to patients with 25(OH)D deficiency; however, the odds ratio was not significant statistically (OR: 0.72; 95% CI: 0.33–0.92 vs OR 2.25, 95% CI: 0.84–6.04). Figure 1 shows the prevalence of ventricular dysfunction and vitamin D deficiency in the study population.

Inflammatory markers (CRP and WBC) as the mediator factors

The four criteria necessary to establish CRP and WBC as the mediators of the association between 25(OH)D deficiency and ventricular dysfunction are listed in Table 3.
The 25(OH)D deficiency was significantly associated with WBC. Moreover, there was a significant association between WBC and ventricular dysfunction. The odds ratio of 25(OH)D deficiency and ventricular dysfunction was attenuated after adjustment for WBC, but not to a clinically meaningful extent. Only one out of four null hypotheses was rejected for CRP as a mediator. Therefore, both WBC and CRP did not meet the criteria of being mediators in the association of 25(OH)D deficiency and ventricular dysfunction.

### Further analysis

The stratified regression analysis for WBC, after adjustment for demographic, clinical, and laboratory characteristics, shows that there was a statistically significant association between WBC and 25(OH)D deficiency. As a result, the next analysis was stratified by WBC. There was no significant association between 25(OH)D concentrations and ejection fraction among patients with normal WBC. However, the unadjusted model for patients with WBC >11,000 showed...
Vitamin D concentration and ventricular dysfunction

the association between 25(OH)D deficiency and ventricular dysfunction; even after adjusting the model for demographic variables, the OR was more than one, which demonstrated that patients with 25(OH)D deficiency were more likely to develop ventricular dysfunction among those with leukocytosis (OR: 2.11, 95% CI: 1.41–6.37). The result remained identical after adding clinical characteristics to the model.

Discussion

Worldwide, ACS is one of the important causes of heart failure. Although the pathophysiology of ACS is not fully understood, evidence suggests that inflammation and endothelial dysfunction are part of the biological pathway to develop ACS.

Studies of the general population have concluded that vitamin D deficiency is associated with diabetes, cardiovascular disease, and poor physical function. Previous reports have suggested that 25(OH)D is a precursor of several hormones which may contribute to cardioprotective function, inflammatory response, and the thrombotic process in the pathogenesis of atherosclerosis.6,13 There is now mounting evidence that explains the role of vitamin D in the functioning of immune regulatory pathways. It has been suggested that there is an association between inflammatory markers such as CRP and/or WBC and 25(OH)D concentrations. In fact, the vitamin D receptor has been identified on inflammatory cells, where the active metabolites of vitamin D inhibit leukocyte proliferation, cytokine release, and the platelet aggregation process.13–16 Our study represents the first attempt to define the impact of serum vitamin D concentration and ventricular dysfunction in consideration of inflammatory marker activity.

Our study found a significant association between 25(OH)D deficiency and increased prevalence of ventricular dysfunction among patients. CRP and WBC did not meet the criteria as the mediators. WBC was an effect modifier: only patients with leukocytosis were found to have a significant association with increased odds of developing ventricular dysfunction. These results suggest that vitamin D concentration could be an important tool in the prediction of ACS.

Figure 1 Left ventricular dysfunction (LVEF <45) among patients with vitamin D deficiency and those with normal serum vitamin D concentration.
by the serum interleukin and tumor necrosis factor (TNF-α).17
In contrast, another study showed that vitamin D administra-
tion among patients with diabetes did not significantly alter
serum biomarkers of inflammation and oxidative stress.19
Moreover, there is contradictory evidence with regard to the
association of CRP and cardiovascular outcomes.20

Our study revealed that 25(OH)D deficiency had a
significant effect on increasing the odds of left ventricular
dysfunction. Correia et al demonstrated the potential asso-
ciation between 25(OH)D and hospital mortality among
patients with ACS.21 Similarly, another cross-sectional study
presented a significant association between serum vitamin D
concentrations and ventricular ejection fraction.22 A link
between vitamin D deficiency and the severe outcomes of
ACS among patients with diabetes has been suggested by
Gondim et al.23 Verdoia et al indicated that low vitamin D
collection is highly associated with adverse outcomes in
women suffering from cardiovascular diseases.24 Survival
analysis for 7-year total mortality rate among patients with
ACS showed a correlation between vitamin D deficiency and
increased rate of mortality.2 A prospective study proposed a
possible association between vitamin D deficiency, elevated
cholesterol levels, and inflammatory markers.25

We found that the prevalence of left ventricular dys-
function was higher among patients with leukocytosis and
25(OH)D deficiency, but not among those with normal
WBC and low serum vitamin D. It is possible that the sys-
temic effect of increasing WBC may alter the association of
vitamin D concentration and ventricular dysfunction through
inflammatory pathways.13,16

Limitations of this study need to be acknowledged. The
cross-sectional design prevents any inferences of causality.
In our study, serum vitamin D concentration and ventricular
ejection fraction were evaluated at a single time point. How-
ever, a cross-sectional design is appropriate for hypothesis
generation. Unmeasured confounders are another challenging
issue. Information about patient health behavior, lifestyle,
and medication history which may influence the ACS prog-
nosis were not measured in our study. Our study included
no variables of socioeconomic factors which may be linked
to vitamin D status.26 Short-term follow-up is also another
limitation in this study. Moreover, this study ignored the
severity of ventricular dysfunction by categorizing ejection
fraction as a binary variable because of small sample size;
future larger studies may benefit from examining ventricular
dysfunction as a non-dichotomized outcome.
