Background: Osteoporosis is a well-known comorbidity in COPD. It is associated with poor health status and prognosis. Although the exact pathomechanisms are unclear, osteoporosis is suggested to be either a comorbidity due to shared risk factors with COPD or a systematic effect of COPD with a cause–effect relationship. This study aimed to evaluate whether progression of osteoporosis is synchronized with that of COPD.

Materials and methods: Data from 103 patients with COPD included in the Hokkaido COPD cohort study were analyzed. Computed tomography (CT) attenuation values of thoracic vertebrae 4, 7, and 10 were measured using custom software, and the average value (average bone density; ABD) was calculated. The percentage of low attenuation volume (LAV%) for each patient was also calculated for evaluation of emphysematous lesions. Annual change in thoracic vertebral CT attenuation, which is strongly correlated with dual-energy X-ray absorptiometry-measured bone mineral density, was compared with that in FEV₁₀⁻ and emphysematous lesions.

Results: In the first CT data set, ABD was significantly correlated with age (p=0.33; p=0.0006), body mass index (BMI; p=0.246; p=0.0136), St George’s Respiratory Questionnaire (SGRQ) activity score (p=0.248; p=0.0115), eosinophil count (p=0.229; p=0.0198), and LAV% (p=0.372; p=0.0001). However, ABD was not associated with FEV₁₀⁻. After adjustment for age, BMI, SGRQ activity score, and eosinophil count, no significant relationship was found between ABD and LAV%. Annual change in ABD was not associated with annual change in LAV% or FEV₁₀⁻.

Conclusion: Progression of osteoporosis and that of COPD are not directly related or synchronized with each other.

Keywords: osteoporosis, quantitative CT analysis, FEV₁₀⁻, low attenuation volume, automatic analysis, systemic effect

Introduction

COPD is characterized by progressive airflow limitation caused by enhanced chronic inflammatory response of the airways and lungs to cigarette smoke. Comorbidities of COPD have recently attracted considerable attention because they have a great impact on disease severity and prognosis and the quality of life of patients.¹ While some comorbidities may arise from shared risk factors, others may be influenced by the features of COPD,² such as systemic inflammation.³

Osteoporosis is a well-known comorbidity in COPD. It is associated with poor health status and prognosis. In patients with COPD, osteoporosis has been reported to be associated with age, low body mass index (BMI), tobacco exposure, physical inactivity,
systemic inflammation, intake of corticosteroids, extent of emphysematous lesions, and FEV$\text{\textsubscript{1.0}}$. Although the mechanisms associated with osteoporosis and COPD are not entirely clear, osteoporosis is suggested to be either a comorbidity due to shared risk factors (eg, age and smoking habits) or a systemic effect of COPD with a cause–effect relationship.\textsuperscript{7}

Emphysematous lesions assessed by computed tomography (CT) and FEV$\text{\textsubscript{1.0}}$ are important indices of COPD which correlate with the severity of COPD and mortality.\textsuperscript{8} Several cross-sectional studies have shown the association of bone mineral density (BMD) with FEV$\text{\textsubscript{1.0}}$ and emphysematous lesions in patients with COPD.\textsuperscript{3–7,9–12}

In this study, we evaluated whether progression of osteoporosis is synchronized with that of COPD. The relationship of annual change in BMD with annual changes in pulmonary function and emphysematous lesions was evaluated.

**Materials and methods**

**Study design and subjects**

This study used data from the Hokkaido COPD cohort study. The aims and design of the Hokkaido COPD cohort study have been described elsewhere.\textsuperscript{13} In brief, the participants fulfilled the spirometric criteria presented in the Global Initiative for Chronic Obstructive Lung Disease (GOLD) documents (ratio of post-bronchodilator FEV$\text{\textsubscript{1.0}}$ to FVC <0.70) more than once within a year from the first visit.\textsuperscript{1} The inclusion criteria were the following: (1) diagnosis of COPD by a pulmonologist; (2) current or former smoker with a smoking history of at least 10 pack-years; (3) age ≥40 years; and (4) willingness to provide written informed consent. The exclusion criteria were the following: (1) diagnosis of bronchial asthma, bronchiectasis, or bullous lung disease; (2) presence of active tuberculosis; (3) history of lung cancer, cystic fibrosis, allergic alveolitis, or pulmonary fibrosis; (4) history of lung resection; (5) long-term oxygen therapy for 12 h or more per day; (6) exacerbation experienced within a month before enrollment for visit 1; and (7) withdrawal of consent.\textsuperscript{13} In the present study, 105 patients who underwent chest CT at least twice between June 2003 and October 2006 at the Hokkaido University Hospital were enrolled. Of the 411 CT images of the 105 patients, 28 images were found to be ineligible for measurement of vertebral bone attenuation; in addition, two patients were excluded because some of their CT images were found to be ineligible. As a result, this study included 383 CT images from 103 patients (Figure 1).

The study was approved by the ethics committee of Hokkaido University and conformed to the tenets of the Declaration of Helsinki, and all participants provided written informed consent.

**Assessment of clinical parameters**

Data regarding gender, age, height, weight, smoking and medical history, medication, and pulmonary symptoms were recorded at the first visit. Changes in smoking status, medical history, and pharmacotherapy were monitored every 6 months. Health-related quality of life was assessed every year using St George’s Respiratory Questionnaire (SGRQ). Blood tests were performed every year for evaluation of circulating blood cell counts and serum immunoglobulin E (IgE) and C-reactive protein (CRP) concentrations.

**Pulmonary function tests and CT**

We confirmed that all respiratory medicines were discontinued before evaluation. Spirometry was conducted on every visit, before and after inhalation of a bronchodilator. Predicted values of spirometric measurements were derived from the guidelines for pulmonary function tests issued by the Japanese Respiratory Society.\textsuperscript{14} Chest CT images were acquired at full inspiration in the supine position. Computerized three-dimensional CT analysis of the lungs was performed using custom software, and the extent of emphysema was expressed as the percentage of low attenuation volume (<−950 Hounsfield units (HU)) (LAV%).\textsuperscript{13,15} Airway lesions were assessed by measuring the square root of airway wall area of the hypothetical airway with an internal perimeter of 10 mm ($\sqrt{Aaw}$ at Pi10), which is a standardized index of airway wall thickness, using Apollo\textsuperscript{®} software (VIDA Diagnostics, Coralville, IA, USA).\textsuperscript{16–19}

**Measurement of CT attenuation of thoracic vertebral bone**

Using the custom software,\textsuperscript{20,21} CT attenuation values of all thoracic vertebral bodies were measured (Figure 2).
The software contains an algorithm for the automatic extraction of vertebral bodies and the measurement of bone densities. The average bone densities of thoracic vertebrae 4, 7, and 10 ($\Delta$ADB$_{4,7,10}$) and of all thoracic vertebrae (ADB$_{1–12}$) were calculated and expressed in HU.

### Statistical analyses

All statistical analyses were performed using JMP9.0.2® software (SAS Institute, Cary, NC, USA). Relationships among the variables were assessed by Spearman’s rank correlation test. Multivariate regression analysis was performed to evaluate the relative contributions of associated factors to ADB$_{4,7,10}$. A mixed-effects model was used for the evaluation of data on all subjects (103 patients). The best linear unbiased predictions of annual changes in FEV$_{1.0}$ ($\Delta$FEV$_{1.0}$; mL/year), LAV% ($\Delta$LAV%, %/year), and ADB$_{4,7,10}$ ($\Delta$ADB$_{4,7,10}$; HU/year) were estimated using a random coefficient regression model. We considered p-values <0.05 to be statistically significant.

### Results

#### Patient characteristics

Table 1 presents the characteristics of the 103 included patients. Seven patients (6.8%) were female, and the median follow-up period was 3 years. With regard to osteoporosis treatment, two patients were prescribed vitamin D, and none was prescribed bisphosphonate at the first visit. There was no change in the prescription for osteoporosis treatment during the study period.

### Relationship between baseline ABD and other variables

$\Delta$ADB$_{4,7,10}$ and ABD$_{1–12}$ correlated well ($\rho=0.982; p<0.001$). However, neither ABD$_{4,7,10}$ nor ABD$_{1–12}$ was associated

with FEV₁,10, annual change in LAV% (ΔLAV%), or FEV₁,10 (ΔFEV₁,10). As shown in Table 2, ABD₁–10 at baseline was significantly correlated with age (ρ=−0.331; p=0.0006), BMI (ρ=0.246; p=0.0136), SGRQ activity score (ρ=−0.248; p=0.0115), eosinophil count (ρ=0.229; p=0.0198), and LAV% (ρ=−0.372; p=0.0001). Similarly to ABD₁–10, ABD₁–12 exhibited significant relationships with age, BMI, SGRQ activity score, eosinophil count, and LAV%. After adjustment for age, BMI, SGRQ activity score, and eosinophil count (variables which exhibited significant correlation with baseline ABD₁–10), the correlation between ABD₁–10 and LAV% was no longer significant (Table 3).

Relationship between ΔABD and other variables

As shown in Table 4, ΔABD₁–10 was not associated with age, BMI, FEV₁,10, ΔFEV₁,10, LAV%, ΔLAV%, or systemic inflammatory factors such as white blood cell count and CRP concentration.

Discussion

In this study, annual change in ABD was not associated with that in LAV% or FEV₁,10 in patients with COPD. At the first visit, ABD was associated with LAV%, which is consistent with the findings of previous studies. However, after adjustment for age, BMI, physical activity, and eosinophil count, LAV% was no longer associated with ABD₁–10. Our findings suggest that progression of osteoporosis and COPD are not synchronized with each other.

Only a few studies have examined the association of annual change in BMD with that in emphysematous lesions or FEV₁,10. Kiyokawa et al observed 42 patients with COPD without osteoporosis treatment for 2 years and concluded that annual change in BMD was not associated with that in low attenuation area percentage or FEV₁,10. The present findings,
which were obtained with a greater number of patients and longer follow-up periods, using a mixed-effects model, help to confirm these previous results.

Several cross-sectional studies have used multivariate models to demonstrate that emphysematous lesions are significantly correlated with BMD in patients with COPD even after adjustment for age, BMI, smoking index, FEV$_{1.0}$, and partial pressure of oxygen in arterial blood. Bon demonstrated in a cross-sectional study that radiographically evaluated emphysema is a strong, independent predictor of low BMD in current and former smokers. Unlike in the present study, the previous author evaluated BMD by dual-energy X-ray absorptiometry and emphysematous change by visual assessment. It has been reported that BMI is negatively correlated with LAV% but not with airway lesions. In this study, √Aaw at Pi10 did not correlate with ABD. This is the only study examining the association between √Aaw at Pi10 and BMD.

Although both BMI and LAV% are correlated with ABD, LAV% was not correlated with ABD after adjustment for BMI. Thus, low BMI may influence both emphysema and osteoporosis in patients with COPD. In this study, eosinophil count was positively associated with ABD; however, after adjustment for age, BMI, SGRQ activity score, and LAV%, this association was no longer apparent. We excluded patients with clinically diagnosed bronchial asthma in this study. We have previously demonstrated that eosinophil count is negatively correlated with annual decline in FEV$_{1.0}$. Patients with COPD with high eosinophil counts may exhibit a different phenotype from patients without high eosinophil counts. Further study is needed.

In this study, we used custom software for measuring bone CT attenuation. Takahashi et al validated this software in 526 cases and found that bone CT attenuation was strongly corrected with dual-energy X-ray absorptiometry-measured BMD ($R^2=0.829$) in patients with COPD.

Some studies on the assessment of bone health status in patients with COPD by measurement of CT bone attenuation have considered the average attenuation values of thoracic vertebrae 4, 7, and 10 (ABD$_{4,7,10}$) for analysis. In the present study, we additionally measured the average attenuation values of all vertebrae (ABD$_{1-12}$). Our results demonstrated that ABD$_{4,7,10}$ and ABD$_{1-12}$ correlated well ($p=0.982$, $p<0.001$). Thus, we thought it sufficient to use ABD$_{4,7,10}$, a previously used parameter, in the measurement of BMD.

Only a few studies have reported on osteoporosis medications for patients with COPD. In previous studies, bisphosphonate was prescribed to 5.8% of 190 smokers and 5.7% and 7% of 210 and 658 patients with COPD, respectively. In the present study, none of the patients was prescribed bisphosphonate, and only two patients were prescribed vitamin D. Systemic corticosteroids also affect BMD. In this study, seven out of 103 patients used inhaled corticosteroids (ICS) and one patient used oral corticosteroids at entry to this study. Eighteen patients began to use ICS and five patients began to use oral corticosteroids after study entry. We excluded these patients and reanalyzed the data. However, the main results did not change.

In this study, seven female patients were included. Since gender differences may affect the correlations between ABD and COPD parameters, we excluded the female patients and analyzed the 96 male patients. The relationships between ABD or ∆ABD and other parameters did not change.

This study has several limitations. First, details regarding prescribed medicines, except for those prescribed for COPD treatment, were not fully available. However, as described in “Patient characteristics” in the Results section, we were able to collect data regarding osteoporosis medications.

Second, clinical data regarding vertebral compression fractures were lacking. It has been reported that CT scan density showed a highly significant positive correlation with pathological measurements of vertebral bone density. However, fracture and deformation of vertebral bodies could affect the ABD. While most of the previous studies on COPD and osteoporosis have not referred to vertebral compression fractures, the TOWards a Revolution in COPD Health study reported a low incidence of fractures (5.1%–6.3%) in patients with COPD during the 3 year study period. Thus, in this study, we visually assessed all CT images for signs of vertebral fracture and found no such instances. In addition, we used our custom software and measured the height of each vertebral body in all subjects. We found three subjects whose vertebral bodies showed more than 20% decrease in height compared with the adjacent vertebral bodies. We then excluded these three subjects from the analysis, but the main result did not change.

Third, the disease duration of COPD may affect ABD. However, we do not have the data about the duration of COPD. Further study is needed to clarify this point.

Notwithstanding the several limitations, the patients were followed up for as long as 4 years, and the median follow-up period was 3 years, which is longer than that reported in previous studies. We also confirmed the present results by evaluating the data on 79 other patients, who were followed up for 3 years or more; the results of both study cohorts were the same. By evaluating a total of 383 CT images (an average of 3.72 CT images per patient), we were able to calculate the annual changes in ABD, LAV%, and FEV$_{1.0}$ using a mixed-effects model.
Conclusion
Progression of osteoporosis and that of COPD are not directly correlated or synchronized with each other.
