Abstract: Late-life depression (LLD) is both a prevalent and life-threatening disorder, affecting up to 13.3% of the elderly population. LLD can be difficult to identify because patients mainly consult their general practitioner (GP) for somatic complaints. Moreover, patients may be hesitant to express the problem to their GP. Increased vigilance on the part of the GP can only benefit older people with depression. To recognize the risk of LLD, screening tools are provided in addition to treatment options for LLD. This review aims to provide the GP with guidance in recognizing and treating LLD. It tries to connect mainstream etiologies of LLD (e.g., vascular, inflammation, hypothalamo–pituitary–adrenal axis) with risk factors and current therapies. Therefore, we provide a basis to the GP for decision-making when choosing an appropriate therapy for LLD.

Keywords: geriatric mental health, major depressive disorder, elder care, psychosomatic, geriatric psychiatry

Introduction
Late-life depression (LLD), with an estimated prevalence of 13.3%, is a common mental health disorder in older people. 1 It is associated with increased morbidity and mortality in addition to a high societal cost. 2 Moreover, the treatment cost of an older person with depression is 1.86 times higher than that of an older person without depression. 3 The consequences of untreated LLD include poor quality of life, exacerbation of chronic illnesses, and suicide. 4 Due to the atypical presentation, the diagnosis is often missed by general practitioners (GPs), which consequently leads to undertreatment of the disease. 5 However, an LLD diagnosis in time can be life-saving and, when treated, LLD has a good prognosis; up to 70% of older patients with depression treated with antidepressants recover from a depressive episode. 6 The aim of this review is to provide a comprehensive and practical guide for GPs with regard to the main risk factors as well as the diagnostic and therapeutic approach to LLD.

Definition of the problem
LLD can be defined as depression that occurs for the first time after age 60. When we use the term “depression”, we refer to major depressive disorder as defined by the Diagnostic and Statistical Manual of Mental Disorders 5 (DSM-5). The cardinal symptoms of major depressive disorder are anhedonia (a loss of interest in activities one used to enjoy) and a depressed mood through most of the day. 7 According to the
DSM 5, an older person has an episode of major depression if he or she has at least one cardinal symptom and four or more of the following symptoms for at least 2 weeks: significant decrease or increase in weight or appetite; insomnia or hypersomnia, fatigue, psychomotor agitation, or retardation; diminished ability to concentrate or make decisions; feelings of worthlessness or inappropriate guilt; and recurrent thoughts of death or suicidal ideation. In the elderly, depressive feelings may often be masked by unexplained physical complaints (e.g., fatigue, diffuse pain or back pain, headache, chest pain, etc.) and, consequently, the classical DSM 5 criteria sometimes seem to fail in terms of diagnosing depression in elders.8

Furthermore, the conditions mentioned above can exist concomitantly. The differential diagnosis of LLD is broad (Table 1). Physical examination and cognitive screening may be useful in ruling out common conditions that are often confused with depression and in assessing for commonly co-occurring diseases. Consequently, a thorough medical history, Mini Mental State Exam, physical examination, and, sometimes, further technical investigations are recommended. Indications for referring patients to a geriatric psychiatrist are presented in Table 2.8

A particularly difficult differential diagnosis of LLD is dementia (see Table 3). Moreover, Parkinson disease (PD) is a prevalent neurodegenerative disease associated with depression and occurs in up to 35% of patients with PD.10 Depression associated with PD is not a single entity, but rather a heterogeneous group of three subtypes where only one group is directly related to the pathophysiology of PD.11 The signs of depression linked to PD include nonresponse to at least one course of antidepressant treatment, absence of suicidal behavior, absence of guilt and self-blame, and no personal history of depression. The pathophysiological mechanism of depression in PD is unknown, but a current hypothesis implies genetic factors, Lewy body pathology, stress-induced hypercortisolemia, inflammation, psychosocial aspects, and changes in monoaminergic signaling.10

In the assessment of LLD, exclusion of somatic causes of depression through patient history, clinical examination, laboratory tests, and/or imaging is the first step in appraising LLD.12 A GP who has good knowledge of the patient’s personality can identify nonverbal cues and changes in behavior suspicious for mood problems.13 In addition, information from family members and/or caregivers on the patient’s mood,
functioning and behavior is crucial for assessing the older person with depression.

There is no golden standard for bringing up depression; it is dependent on the physician’s manner, and research on the topic is lacking. To engage the patient, the use of the bio-psychosocial model may be helpful: inform the patient that the illness is an interaction between physiological (e.g. serotonin hypothesis), psychological, and social factors.14

Risk factors
The risk factors for LLD are a combination of biological and psychosocial factors.

Biological risk factors
The biological risk factors associated with LLD are old age and female sex.15 In addition, there may be a genetic vulnerability, making some people more susceptible to LLD than others.16

Patients with poor physical health (e.g. multiple comorbidities, sleeping disorders, etc.) may be predisposed to LLD.17 These people often use more medication, which in itself is a risk factor for LLD.18

The concept of frailty stresses a loss of function in several domains of functioning (not only the physical), leading to a decline in the reserve capacity for dealing with stressors. Frailty can be defined by the Fried criteria: weight loss, decreased handgrip strength, slowness, exhaustion, and low physical activity.19 Physical frailty is linked to chronic inflammation and LLD.20,21 Poor nutritional status is associated with frailty; therefore, nutritional supplements (vitamin D and proteins) could benefit the depressed frail patient.22 Nutritional deficits that are often reported in older people with depression are vitamin B12 and folate deficiencies.23 The current hypothesis states that vitamin D affects mood by interacting with brain receptors in the limbic structures and hippocampus.24

Neurodegenerative disease (e.g., PD or Alzheimer) and mild cognitive impairment (MCI) has also been considered a possible risk factor for LDD.25 There are hypotheses that LLD may lead to MCI and, consequently, dementia.25 The debate is still ongoing, and the current literature is inconclusive about LLD being a prodrome of dementia.27 What we do know is that LLD and dementia frequently co-occur, and depression can be the first sign of dementia.28,29

The vascular hypothesis states that cerebrovascular disease may cause or predispose to LLD. The concept of vascular depression as a clinical entity is inherently linked to this hypothesis and can be explained by reduced cerebral perfusion, altered brain connectivity due to vascular brain lesions, and chronic low-grade inflammation.30 LLD has been linked to atherosclerosis, which is – at the same time – the leading cause of coronary heart disease.31

Psychosocial risk factors
Kaji et al point out that psychological factors such as loss of purpose in life or human relationships seem to be associated with LLD.32 Moreover, lower education has been linked to LLD.33 Being a widower or single is a risk factor for LLD.34 Being functional or visually impaired increases the risk of developing LLD.35

Poor lifestyle habits can put elders at risk for LLD. Both smoking and alcohol use are the risk factors of LLD.18

Differential diagnosis: late-life depression versus dementia

Onset: Slow or acute versus Slow and progressive onset.
Evolution: Chronological order of events can be recalled versus History of the disease cannot be restored by the patient.
Quality of life: Decreased versus The patient does not experience his/her disease as a problem.
Memory: Decreased ability to think or concentrate or being slowed down versus Decreased able to learn new information or to recall previously learned information.
Language and praxis: Normal versus Patient tries to hide cognitive problems.
Affect: Apathetic, depressed mood, psychomotor retardation versus Decreased.
Somatic: Sleep disturbances versus Lability of affect.
Somatic problems (insomnia, dizziness, pain, etc.) versus Can be present, but will not be chief complaint.
Low energy versus
Diurnal mood variation versus

Prognosis: Treatable versus Irreversible.
addition, the use of sleep medication has been linked to LLD, but sleep disturbance in general is a risk factor for LLD.35

Screening

In the following text, we only discuss screening tools validated in a geriatric and primary care setting. These tools should not be used systematically; rather, an opportunistic screening is advised in patients whom LLD is suspected. In Table 4, we compare the Geriatric Depression Scale (GDS), Center for Epidemiologic Studies Depression Scale (CES-D), and Patient Health Questionnaire 2 (PHQ-2).

Approach

The recommended approach to LLD is stepped care: treatment is based on the severity of depression and preference of the.42 The severity of the depressive disorder (mild, moderate, or severe) is based on the number of symptom criteria, the severity of those symptoms, and their functional disability in the DSM-5. If the selected treatment for LLD is inadequate, the GP should step up and provide the next step of treatment (see Figure 1). A summary of risk factors, screening tools, and interventions are provided in Table 2.

Prevention

The risk factors that can be modified are nutritional deficiencies and cardiovascular disease, which are more common at older ages.43,44 Vascular risk factors can be improved by exercise, diet, smoking cessation as well as treatment for hypertension, hypercholesterolemia, and hyperglycemia.45,46 These inter-

Figure 1 Stepped care approach to late-life depression, based on the severity of depression and patient preference. Initiate the next step if the patient does not respond to the therapy.
Nonpharmacological treatment

Psycho-education

The GP plays a central role in providing psycho-education: to clarify major depressive disorder, to explain therapeutic options, discuss biopsychological vulnerability, to teach to recognize warning signs, and to inform and support the spouse. In addition, the primary physician actively monitors the patient through frequent visits. Moreover, the primary physician tries to provide a structure in the patient’s life and activate the patient through structured and fun activities. The structure provided must be manageable for the patient and should lead to positive feelings. A balance between tasks and relaxation is essential. Healthy food, sufficient sleep, and daily interactions are a prerequisite.

Behavioral activation

Structured physical activity is recommended for older people with mild or moderate depression who are physically capable and can be motivated to exercise. Exercise is safe and effective in addition to the pharmacological treatment of depression. Mere referral of an older person with depression is not enough. Primary care physicians and psychiatrists should take an active role in keeping the patient motivated and managing the exercise-related adverse effects. A recent meta-analysis recommends structured, supervised exercise programs, three times a week (45–60 min), over 10–14 weeks, and at low intensity for mild to moderate depression.

Psychotherapy

Psychotherapy is the most important type of nonpharmacological treatment. In LLD, psychotherapy decreases depressive symptoms in older people with depression. Psychotherapeutic interventions can prevent LLD in older people with sub-syndromal depression and are not inferior to pharmacological treatment. Evidence-based psychotherapeutic treatments of depression in older adults include cognitive behavioral therapy (CBT), problem-solving therapy (PST), reminiscence therapy, and interpersonal therapy (IPT). One relatively new therapy is life review therapy, where the patient shares and talks about important life events and memories with their therapist. A randomized controlled trial (RCT) proved that life review therapy is effective in depressed older adults and also reduces anxiety. In addition, life review therapy has already been implemented with success in a structured multidisciplinary approach in nursing homes and led to reduced prevalence of depression.

Pharmacological treatment

Older adults have different pharmacodynamics and pharmacokinetics due to age-related physiological changes. Medication must be administered at lower doses or slowly titrated while actively monitoring the patient. Patients with comorbidities usually take multiple drugs. Increased vigilance for drugs interactions is, therefore, necessary. A careful review of the patient’s drug history is recommended. Moreover, when choosing a psychotropic drug, one needs to keep track of the drug’s safety profile. Because falls can invalidate old adults and even lead to increased mortality (hip fracture), avoid medications that sedate the patient.

In primary care, both tricyclic antidepressants (TCAs) and selective serotonin reuptake inhibitors (SSRIs) are the pharmacological treatments of choice. Existing evidence suggests that no one class of antidepressant drugs has been found to be more effective than another in the treatment of LLD. Although newer antidepressants are not more effective than older ones, they are better tolerated and are safer, especially in cases of overdose. The adverse effect data suggest the modest superiority of SSRIs over TCAs. When choosing an SSRI, slight preference goes to an SSRI with less anticholinergic side effects, such as nortriptyline or (es) citalopram. Citalopram has a Food and Drug Administration (FDA) black-box warning for increased risk of arrhythmia (QTc prolongation), which is why sertraline is preferred over citalopram. TCAs are as effective as SSRIs for LLD, but are less often used because of frequent side effects. TCAs with lesser anticholinergic side effects, such as nortriptyline, are recommended by the authors. Both SSRIs and TCAs are associated with fracture risk, although causality is not proven.

Serotonin and noradrenaline reuptake inhibitors (SNRIs; e.g., duloxetine, venlafaxine) are an alternative to SSRIs for depressed older adults when SSRIs are ineffective or contraindicated. SNRIs are not only effective against the major depressive disorder but also effective in the treatment of peripheral neuropathic pain.

Another second-generation antidepressant that can be used as an alternative for SSRIs is mirtazapine. The sedative side effects of mirtazapine are used as a treatment for...
insomnia. In addition, mirtazapine improves the appetite and can be used for anorexia. The effect of mirtazapine on sodium levels is limited, and therefore, less hyponatremia is noted in patients taking mirtazapine.4

Important and frequent side effects and contraindications of antidepressants are reported in Table 5.

**Electroconvulsive therapy**

An effective treatment for LLD, available from mental health specialists, is electroconvulsive therapy (ECT). In ECT, an electrical stimulus is given for a brief period to produce a generalized seizure. Multiple RCTs have proved that ECT is beneficial for LLD, especially psychotic depression, treatment-refractory depression, catatonia, and depression with severe weight loss and anorexia. ECT is an effective and safe treatment for depression in adults, including the oldest elders (≥80 years). Recent evidence suggests old age is a positive predictor of response to ECT: it gives faster and higher remission rates as compared to antidepressants. A meta-analysis of the cognitive effects of ECT suggests its relative safety and the transient character of its effects on memory. Autobiographical memory is affected by ECT, but restored or improved 6 months after treatment. Compared to antidepressants, ECT induces a higher speed of remission.4

**Conclusion**

LLD is a prevalent disease that often presents with atypical symptoms and more somatic (co)morbidities and complaints. A stepped care model to treat depression is advised, taking into account the severity of the depression. Due to the somatic (co)morbidities, a collaborative care model is preferred. The collaborative care model has proven efficacy and cost-effectiveness in LLD.
