Clinical and Experimental Gastroenterology 2008:1 19–47

Abstract: Sporadic colon cancer is caused predominantly by dietary factors. We have selected bile acids as a focus of this review since high levels of hydrophobic bile acids accompany a Western-style diet, and play a key role in colon carcinogenesis. We describe how bile acid-induced stresses cause cell death in susceptible cells, contribute to genomic instability in surviving cells, impose Darwinian selection on survivors and enhance initiation and progression to colon cancer. The most likely major mechanisms by which hydrophobic bile acids induce stresses on cells (DNA damage, endoplasmic reticulum stress, mitochondrial damage) are described. Persistent exposure of colon epithelial cells to hydrophobic bile acids can result in the activation of pro-survival stress-response pathways, and the modulation of numerous genes/proteins associated with chromosome maintenance and mitosis. The multiple mechanisms by which hydrophobic bile acids contribute to genomic instability are discussed, and include oxidative DNA damage, p53 and other mutations, micronuclei formation and aneuploidy. Since bile acids and oxidative stress decrease DNA repair proteins, an increase in DNA damage and increased genomic instability through this mechanism is also described. This review provides a mechanistic explanation for the important link between a Western-style diet and associated increased levels of colon cancer.

Keywords: bile acids, genomic instability, colon cancer

Introduction

Sporadic colon cancer is caused predominantly by dietary factors, most notably a high-fat diet accompanied by low intake of micronutrients (folate, niacin, zinc), antioxidants and other plant phytochemicals. A high intake of fat induces the release of bile acids from the gall bladder into the small intestine. Bacteria in the colonic lumen then convert conjugated and hydrophilic bile acids to unconjugated, hydrophobic bile acids such as deoxycholic acid and lithocholic acid (Figure 1). These hydrophobic bile acids, deoxycholic acid in particular, have been reported to be multiple stress inducers and at high physiologic levels can create chaos within colon epithelial cells. These stresses include membrane perturbation, oxidative DNA damage, decrease in DNA repair proteins, mitotic stress, micronuclei formation, mitochondrial damage (metabolic stress) and endoplasmic reticulum (ER) stress (Figure 2).

Although excessive stress will lead to apoptosis, this altruistic act of removing DNA-damaged cells for the survival of the organism becomes largely circumvented in cells with activated survival pathways. In this “war zone”, stimulated by the presence of hydrophobic bile acids, mutated epithelial cells may act in a selfish manner, like bacterial cells, and Darwinian selection can come into play at the cellular level. The very stress-response pathways that result in cell survival (eg, activation of nuclear factor-kappa B [NF-κB], autophagy) (Figure 3) can become constitutively upregulated through clonal selection of mutated cells, and can serve to propagate cells even with unrepaired DNA damages and genomic instability. Although it has been known for decades (using animal
models of carcinogenesis) that hydrophobic bile acids can promote colon cancer,11–14 the evidence is now convincing that bile acids are also carcinogens.15–17 Evidence that bile acids are carcinogens in human gastrointestinal (GI) cancers has been reviewed by Bernstein and colleagues.15 Proof that hydrophobic bile acids cause mutation in vitro in epithelial cells of the GI tract was provided by the elegant studies of Jenkins and colleagues.16,17 Even though proliferation is essential to cancer development, it is not the high level of proliferation itself that is responsible for cancer. For example, adenocarcinomas are infrequent in the small intestine, although the proliferation rate of epithelial cells at this site is similar to that of the epithelial cells of the colon. The colon may be particularly susceptible to cancer because it contains tissues that are often exposed to unique stresses (e.g., high levels of hydrophobic bile acids resulting from anaerobic bacterial metabolism). Since there may be insufficient time for DNA repair in this “war zone”,18 the selection of mutated cells with a proliferative advantage may occur repeatedly. This proliferative advantage may take the form of apoptosis resistance and/or increased cell division.

How, in particular, do bile acids contribute to colon carcinogenesis? Since somatic mutation rates are normally too low to account for the high incidence of colon cancers, it has been proposed that genomic instability (i.e., a mutator phenotype) plays a major role in producing the plethora of random genomic changes needed to produce a malignancy.19–21 A mutator phenotype can explain the complex histopathology
Role of bile acids in colon carcinogenesis and behavior of tumors, including different tumor subsets, divergence of clonal populations, and different molecular pathways that may be selected during colon cancer progression and lead to different clinical outcomes. Genomic instability in cancer appears in three major forms: (i) aneuploidy, in which entire chromosomes are gained or lost, (ii) intrachromosomal instability, characterized by insertions, deletions, translocations, amplifications, and other forms all sharing the feature of utilizing DNA breakage as an early step, and (iii) point or oligobase mutations. Genomic instability is a dynamic process in which the three major forms of genetic instability may co-exist at different stages.

**Figure 2** Schematic diagram indicating some of the hydrophobic bile acid (HBA)-induced signaling pathways that begin with the activation of surface enzymes, the subsequent generation of ROS, and the resultant stresses/damages that, if excessive, result in cell death. The most well documented deleterious effects of HBAs in colon cells are DNA damage, mitochondrial stress and ER stress. DNA damage results in the activation of mitotic checkpoint proteins leading to growth arrest. Mitochondrial damage results in the activation of caspases and the cleavage of multiple substrates in the cell. ER stress activates several pro-apoptotic molecules that result in cell death. Repair processes responsive to DNA damage, mitochondrial stress and ER stress can deplete the energy reserves of the cell, resulting in “metabolic stress”. Too much stress on the cell results in cell death through mechanisms that involve apoptosis, necrosis, and/or autophagy. HBA-induced mitotic stress can lead to abnormal cell division. Excessive mitotic stress may lead to mitotic catastrophe and cell death, although the details of this mode of cell death have not been well described. Necrotic cells induced by HBA may, especially, elicit an inflammatory response in vivo, and this could explain, in part, the induction of colitis by chronic feeding of HBA in mouse models. See text for details.

**Abbreviations:** AA, arachidonic acid; COX, cyclooxygenase; PKC, protein kinase C; PLA₂, phospholipase A₂; LOX, lipoxygenase; ROS, reactive oxygen species; XO, xanthine oxidase.
Figure 3 Schematic diagram illustrating a probable sequence of events resulting from exposure to high levels of hydrophobic bile acids (HBAs) that accompany a high-fat diet. This exposure leads to HBA-induced generation of ROS/RNS, activation of survival pathways (eg, autophagy, NF-κB), the generation of cells with genomic instability (eg, mutations, aneuploidy) and clonal selection of mutant cells with survival and proliferative advantages. The end results are the production of adenomas that progress to colon cancer. The epithelial cells of the colon of a person on a Western-style (high-fat/low vegetable/low micronutrient) diet are probably in a persistent “war zone” (bombardment with HBA-induced ROS/RNS, presence of food carcinogens, toxins, etc.). Cells in different stages of progression to malignancy are thus persistently receiving damages to their genome, resulting in clones of cells that are selected for survival in the adverse environment of the colon. While cells in the previous population, if receiving excessive DNA damage, underwent cell death altruistically for the overall benefit of the organism, the new clones of cells may behave selfishly. The new clones may acquire resistance to apoptosis and undergo clonal selection on the basis of their survival advantage, even when their DNA is damaged and after their genomes become unstable. This allows progression to adenomas and colon cancer.

of colon carcinogenesis, providing support for the chaotic roots of neoplastic development and continuous growth of aberrant clones.32,33

Mutations, aneuploidy or other chromosomal aberrations affecting genes that govern genetic stability5,34–37 could be the cause of a mutator phenotype.38,39 The occurrence of a mutator phenotype would be made more likely by conditions that cause DNA damage, such as increased oxidative stress, due to persistent exposure to high levels of bile acids that accompanies a high-fat diet. Increased levels of oxidative stress caused by defective mitochondria have been proposed as a possible mechanism by which a “mutator phenotype” could arise.40 As discussed below, bile acids cause oxidative DNA damage, double-strand DNA breaks (evidenced by activation of phosphorylated H2AX41), aneuploidy,16,17 broken chromosomes16,17 and aberrant mitoses (unpublished data from our laboratory). In addition, high concentrations of bile acids in the lumen provide a persistent stressful environment that may select for mutated cells that can better survive in that environment (Figure 3). Hydrophobic bile acids thus may serve to both initiate and propagate the mutator phenotype. Cycles of aneuploidization42 coupled with specific mutations (eg, APC, ras, p53) and large-scale structural alterations to chromosomes (eg, nonreciprocal translocations, inversions, deletions and insertions resulting in “genome scrambling”43) may then give rise to a population of cells with multiple karyotypes and genotypes. The clonal selection of cells with particular karyotypes and/or mutations may then produce a “field defect” or “field cancerization” associated with gene expression changes. Frequently, one of the selected genotypes will be apoptosis resistance as found in the normal-appearing flat colonic mucosa of humans44,45 which is by definition a “survival genotype”. Within such a field defect, further mutations may then be selected for increased proliferation, altered cell-cell interactions and/or migratory behavior. On this basis a neoplastic clone can emerge (eg, as found in flat adenomas and polyps). These neoplastic survival karyotypes may undergo further mutation and selection to produce a cancer.

This review emphasizes the plethora of cellular stresses imposed by hydrophobic bile acids. Our review provides possible mechanisms by which a high-fat diet can lead to the development of sporadic colon cancers. The roles of mutations in critical genes (eg, APC, ras, p53) during colon carcinogenesis was previously addressed in the insightful discussions by the Vogelstein group46–48 and will not be discussed in this review.

Hydrophobic bile acids generate cellular reactive oxygen species (ROS) and reactive nitrogen species (RNS) that damage DNA and proteins. These damages can lead to genomic instability (eg, point mutations and aneuploidy).49 Point mutations, aneuploidy, and other gross structural alterations of chromosomes (eg, balanced or unbalanced translocations, dicentric chromosomes) appear to interact to produce the unstable and/or aberrant genomes associated with colon carcinogenesis. Aneuploidy is observed in most cancers, although it is not ordinarily found in colon tumors that have a mismatch repair deficiency and display microsatellite instability.50 A small subset of colorectal tumors display microsatellite instability, whereas the rest of colorectal tumors display numerical and/or structural chromosomal alterations as the most prominent outcome of genetic disruption.51

Loss of heterozygosity (LOH) of a portion of a chromosome or a whole chromosome is already evident at the adenoma stage of colon carcinogenesis52–65 and is prominent at the colon cancer stage.59,60,62,63,66–68 A review of the literature indicates that at least 19 of the 22 human somatic chromosomes exhibit aneuploidy during the adenoma to colon cancer stage. The loss or gain of whole or portions of chromosomes involves thousands of genes.69 This chromosomal imbalance could have dramatic effects on cellular homeostasis, including an increase in oxidative/redox state of the cell and the loss of key DNA repair and pro-apoptotic proteins. Approximately 11,000 genomic events were identified in sporadic colonic polyps using the technique of inter-simple sequence repeat polymerase chain reaction (PCR), indicating that genomic destabilization is an early event in sporadic tumor development.31

Pre-neoplastic lesions smaller than adenomas are referred to as aberrant crypt foci (ACF).70–72 The ACF are not identified during routine colonoscopies since vital stains are often not used and biopsies are not usually taken of the flat colonic mucosa. However, human ACF have unequivocally been shown to exhibit genomic instability, including LOH.72–76 Since numerous genetic alterations and aberrant mitotic changes are also observed in the nonneoplastic colon of mice77 and humans78–82 at high risk for colon cancer, biomarkers based on aberrant karyotypes have promise for identifying high-risk individuals. Figures 2 and 3 are based on data from our laboratory and those of others and emphasize the role of hydrophobic bile acids in the induction of multiple stresses and genomic instability. We have selected bile acids as a focus of this review since bile acids play a key role in colon carcinogenesis. We describe how bile acid-induced stresses cause cell death in susceptible cells, contribute to
genomic instability in surviving cells, impose Darwinian selection on survivors in a “war zone” and enhance initiation and progression to colon cancer. This review provides a mechanistic explanation for the important link between a Western-style diet and associated increased levels of colon cancer. However, other factors such as smoking, food-related carcinogens, long-chain fatty acids (eg, palmitic acid), excess iron, arsenic, viruses, bacteria, inflammatory cells, low dietary micronutrients, low omega-3 fatty acids, etc., may also contribute to genomic instability-based carcinogenesis.

**Bile acids cause membrane perturbation**

It has been known for over thirty years that bile salts perturb plasma membranes, and that deoxycholate is more membrane-damaging than cholate and its conjugates. Binding of bile acids with rat colon and the resultant perturbation of membrane organization was later measured using 31P nuclear resonance spectroscopy. Deoxycholate alters membrane composition, as evidenced by a significant upregulation in membrane cholesterol and phospholipids. These findings were mimicked by other hydrophobic molecules unrelated to bile acids, such as sodium lauryl sarcosine and cholesteryl hemisuccinate, strongly implicating hydrophobicity as an important determinant of bile acid effects on signaling. Deoxycholate also perturbs membrane structure by altering membrane microdomains. Depletion of membrane cholesterol by treating cells with methyl-β-cyclodextrin suppressed deoxycholate-induced apoptosis, and staining for cholesterol with filipin showed that deoxycholate caused a marked rearrangement of this lipid in the membrane. Additionally, fluorescence anisotropy studies indicated that deoxycholate caused a decrease in membrane fluidity consistent with the increase in membrane cholesterol content measured after deoxycholate treatment.

Bile acids activate surface enzymes, such as phospholipase A2 (PLA2), epidermal growth factor receptor (EGFR), Fas receptor, protein kinase C (PKC), bile acid receptor M-BAR/TGR5 (G-protein-coupled receptor), phospholipase C (PLC), nicotinamide adenine dinucleotide phosphate (NAD(P)H) oxidase and the Na+/K+-ATPase. We found that the surface enzymes, Na+/K+-ATPase and NAD(P)H oxidase are involved in activating NF-κB, a redox-sensitive transcription factor upregulated during the development of apoptosis resistance in colon cancer cells, and associated with colon carcinogenesis. The activation of surface and other enzymes through membrane perturbation is, therefore, responsible for modulating signal-transduction pathways in colon cells.

The fact that hydrophobic bile acids cause secretory diarrhea (diarrhea is the most common and debilitating symptom of patients with ulcerative colitis [a pre-neoplastic condition of the colon]), warrants a greater effort to understand how these bile acids induce changes in ion transport. Taurodeoxycholic acid, for example, increases electrogenic Cl− secretion into the proximal colonic lumen. This stimulated secretion is believed to occur via an increase in intracellular Ca++ concentration. Deoxycholic acid reduces transepithelial Na+ absorption by inhibiting amiloride-sensitive Na+ channels, and increasing secretion of Na+, K+, and Cl− ions in the distal colon. Hydrophobic bile acids have been reported to act as calcium ionophores, most probably by partitioning bile acid/Ca++ complexes into the hydrophobic core of the membrane bilayer and/or Ca++-transporting channels. We have recently reported that high cytosolic Ca++ levels are a major factor in the activation of NF-κB in HCT-116 colon cells by bile acids.

Two agents (EGTA and Ruthenium Red (RuR)) used in that study prevented NF-κB activation by bile acids through at least two different mechanisms. EGTA does not cross cell membranes and chelates Ca++ ions in the extracellular milieu, thereby preventing Ca++ entry into the cell. RuR is an inorganic polycationic dye that inhibits Ca++ influx through voltage-sensitive calcium channels and blocks the release of Ca++ from the ER.

**Bile acids cause oxidative and nitrosative stress in colon cells**

Bile acids induce production of ROS and RNS in colon epithelial cells. Bile acids generate ROS and RNS by several different pathways, as reviewed by Bernstein and colleagues and summarized here. Bile acids damage mitochondria and damaged mitochondria can “leak” electrons from the electron transport chain to form superoxide (O2−). ROS can also be generated by bile acid activation of PLA2, which releases arachidonic acid from the cell membrane. Arachidonic acid may then be acted on by cyclooxygenase and lipooxygenase to release ROS through partial reduction of O2, during the conversion of arachidonic acid to prostaglandins and leukotrienes.

Deoxycholate activates the redox-sensitive transcription factor NF-κB in colon epithelial cells. When NF-κB is activated it can induce an increase in nitric oxide synthase.
Role of bile acids in colon carcinogenesis

Oxide synthase 2 (NOS2), an enzyme that can generate micromolar quantities of NO. We have found that repeated exposure of HCT-116 colon epithelial cells to increasing concentrations of deoxycholate results in the consistent upregulation of S-nitrosylated proteins. Some of these post-translationally modified proteins were identified by mass fingerprinting analysis and found to include cytoskeletal proteins, metabolic enzymes, signaling proteins, chaperones, redox-related proteins and differentiation-related proteins.\textsuperscript{114} We also found that feeding mice deoxycholate can induce inflammation in a mouse model,\textsuperscript{115} and that the inflammation is mediated in large part by RNS, since colitis is markedly attenuated in NOS2 knockout mice.\textsuperscript{116}

**DNA repair proteins can be modulated by oxidative stress and deoxycholate**

The promoting and mutagenic effects of bile acids can be explained, in part, by a decrease in DNA repair proteins. Since oxidative stress is known to reduce expression of DNA repair proteins, bile acid-induced decreases in DNA repair proteins may also be through an oxidative mechanism. The cell types and experimental conditions in which oxidative stress decreases DNA repair proteins, and bile acids decrease proteins involved in 6 different DNA repair pathways are described below. Since DNA repair proteins often have multiple functions in the cell in addition to DNA repair, such as participation in apoptosis\textsuperscript{126,127} and regulation of mitosis\textsuperscript{126,127} and checkpoint pathways,\textsuperscript{128} a deleterious effect of bile acids on DNA repair protein expression can have important and varied implications for inducing genomic instability.

**Oxidative stress causes a decrease in DNA repair proteins**

Langie and colleagues,\textsuperscript{129} working with human pulmonary epithelial cells A549, showed that oxidative stress caused a reduction in mRNA for the nucleotide excision repair (NER) enzyme ERCC1 as well as a reduction in NER capacity that correlated with level of ERCC1 mRNA. Feng and colleagues,\textsuperscript{130} using the human colon epithelial cell line HCT-116 and the human hepatic fetal epithelial line CL-48, showed by in vitro DNA repair synthesis and host cell reactivation assays, that ROS also inhibit NER through production of malondialdehyde. This effect is likely mediated by malondialdehyde-induced inactivation of DNA repair proteins. Furthermore, as shown in the human erythroleukemia HEL cell line, oxidative stress inactivates the mismatch DNA repair proteins MSH2 and Pms2 (but not MSH2 or MLH1).\textsuperscript{131} In HeLa cells and the human Boleth lymphoblastoid cell line, the base excision repair enzyme OGG1 is degraded or reversibly inactivated following oxidative stress.\textsuperscript{132,133}

In mitochondria, DNA polymerase γ is responsible for both mtDNA replication and repair. In an SV40-transformed human fibroblast cell line, the functional ability of the catalytic p140 subunit of DNA polymerase γ is reduced by oxidative stress.\textsuperscript{134}

**Bile acids decrease DNA repair proteins**

**Short term exposure to deoxycholate decreases the expression of the DNA repair proteins p53 and BRCA1**

The enzyme p53 has multiple roles in the cell. In particular, it has roles in 6 different DNA repair pathways: (1) homologous recombinational repair, (2) nonhomologous end joining, (3) base excision repair, (4) nucleotide excision repair, (5) mismatch repair, and (6) transactivation of expression of O\textsubscript{6}-methyl-guanine-DNA-methyl-transferase for direct repair of alkyl adducts at the O\textsubscript{6}-methyl-guanine position.\textsuperscript{125,135} While treatment of colon HCT-116 cells with non-cytotoxic (200 μM) deoxycholate concentrations increases mRNA expression of the p53 gene, the level of p53 protein is decreased by 40% through proteasome-mediated degradation.\textsuperscript{136} Although mutations in p53 are a late event in colon carcinogenesis, the persistent decrease in p53 function by deoxycholate may have similar consequences as that of a mutation. Work from our group has also shown that deoxycholate decreases BRCA1 at the protein and mRNA levels.\textsuperscript{137} BRCA1 has a key role in recombinational repair of DNA damages, and also regulates the function of the centrosomes which carry out mitotic chromosome segregation through spindle organization.\textsuperscript{127} Failure to adequately repair DNA damages can lead to replication errors and thus mutation; and failure of mitotic segregation can lead to aneuploidy. Since BRCA1 expression is also reduced in colon adenocarcinomas,\textsuperscript{137} it is possible that the modulation of expression of DNA repair enzymes by dietary-related factors may, in part, be responsible.

**Long term exposure of colon cells to deoxycholate selects for decreased protein or mRNA expression of DNA repair proteins**

Three HCT-116 colon cell lines were developed in our laboratory for stable resistance to bile acids by repeated
exposure to increasing concentrations of deoxycholate over a period of approximately 40 weeks. These cell lines were found to have constitutively decreased protein expression of the DNA repair enzymes MSH3 (mismatch repair), Ku80 (non-homologous end joining), P36/MAT1 (nucleotide excision repair) and XPA (nucleotide excision repair). These cell lines were also found to have decreased expression at the mRNA level for ATM (homologous recombination repair), MSH3 (mismatch repair) and XRCC4 (non-homologous end joining).

**Exposure of cholangiocytes to glycochenodeoxycholate (GCDA) decreases DNA repair enzymes**

Komichi and colleagues exposed immortalized mouse cholangiocytes to 200 μM glycochenodeoxycholate (GCDC) for 4 weeks and then performed a microarray gene expression analysis. mRNA expression of OGG1 and MUTYH was downregulated 0.8-fold after exposure to CGDC compared to control cells.

**Bile acids cause DNA damage in colon cells**

Bile acids induce DNA damage in cells of the colon. One type of induced damage in colon cells is oxidative DNA damage, suggesting that oxidative stress is a significant cause of the overall bile acid-induced DNA damage in the colon. Exposure of rat colon ex vivo with high physiologic concentrations of bile acids resulted in the activation of poly(ADP-ribose) polymerase (PARP). PARP is activated by DNA strand breaks and attaches a polymer of ADP-ribose units to proteins which modulates their functional activity and assists in the opening up of the chromatin to allow for more efficient DNA repair. It is probable that the increase in DNA strand breaks is mediated, in part, through the bile acid-induced increase in ROS and/or RNS. Treatment of human colonic biopsies ex vivo with deoxycholate also resulted in the activation of phosphorylated H2AX, implying the generation of double-strand breaks in DNA. Double-strand breaks can cause chromosome breakage with the generation of micronuclei upon exit from mitosis. Increased DNA damage may be caused by the bile acid-induced decrease in DNA repair enzymes (see bile acids decrease DNA repair proteins, above).

**Bile acids cause mutation**

The repeated observation that bile acids cause DNA damage in colon cells suggests that bile acids also increase the incidence of mutation, since replication of a damaged DNA template strand frequently results in a replication mistake, and thus a mutation. Bile acids have been shown to induce mutation in esophageal cells in culture and in vivo in rat esophageal cells. When cultured esophageal cells were treated with deoxycholate, an increase in the frequency of GC to AT mutations in the p53 gene was observed. In other experiments, Big Blue F1lacI transgenic rats were subjected to esophagogastroduodenostomy, a surgical procedure that increases duodenogastroesophageal reflux. In these surgically altered rats, the frequency of mutant lacI cells of the esophageal mucosa was significantly greater than in the control rats that were not subjected to surgery. Thus, components of refluxate, such as bile acids, appear to cause mutation. Forty-six percent of the mutant esophageal cells were altered at CpG dinucleotide sites, and most of these mutations (61%) were C to T or G to A transitions. This pattern of mutation seen in the surgical model approximates that seen in human esophageal adenocarcinoma, suggesting that duodenogastroesophageal reflux is carcinogenic. In surgically treated Big Blue mice (rather than rats) that were altered to increase duodenogastroesophageal reflux, increased mutagenesis was also observed. In another rat model of colon carcinogenesis based on exposure to azoxymethane, deoxycholate increased both the incidence of colon tumors and the incidence of tumors with K-ras mutations. This finding suggests that deoxycholate may induce K-ras mutations. In a sensitive bacterial fluctuation test based on the Ames Salmonella test system, bile acids were also found to be mutagenic.

**Hydrophobic bile acids induce aneuploidy and micronuclei formation**

The induction of aneuploidy by deoxycholate was first reported 26 years ago by Assinder and Uphall in a heterozygous diploid strain of Aspergillus nidulans. The detection of aneuploidy was made possible by the unique orientation of mutations on the chromosomes. Each pair of homologues carried mutations, in repulsion, in at least 2 gene loci, those in linkage groups I, III, IV, and V being on opposite sides of the centromere. This orientation allowed a distinction between cross-over and nondisjunctional segregants (aneuploids). It was suggested that aneuploidy was a result of interference with the normal functioning of the mitotic apparatus through disruption of the nuclear membrane. Ferguson and Parry confirmed that bile acids, including deoxycholate, were potent inducers of aneuploidy using the diploid yeast, Saccharomyces cerevisiae. The assay used...
Persistent exposure of colon cells to deoxycholate results in the modulation of expression of chromosomal maintenance/mitosis-related genes

The induction of aneuploidy with the formation of micronuclei after cells exit mitosis may be caused by a number of defects during cell division. Defects such as insufficient or excessive sister chromatid cohesion,159,160 kinetochore-microtubule attachment defects,161,162 failure of DNA damage checkpoints,163 failure of spindle checkpoints,164–166 telomere defects167,168 and aberrant centrosomal organization and multiplicity169,170 may result in an incorrect number of chromosomes in daughter cells after mitosis. These defects coupled with chromosome breaks can produce an aberrant karyotype that may be carcinogenic. We, therefore, searched for the aberrant expression of mitosis-related genes in colon epithelial cells and colonic tissues that were modulated by deoxycholate. cDNA microarray (Table 1) and proteomic analyses (Table 2) of HCT-116 cell lines persistently exposed to increasing concentrations of deoxycholate in vitro98,138 and cDNA microarray analysis of colonic tissue of wild-type mice receiving dietary supplementation with deoxycholate in vivo115 (Table 3) indicate that deoxycholate modulates the expression of numerous genes associated with mitosis and chromosome maintenance. The list includes 71 genes/proteins associated with cohesion and segregation of chromosomes, telomeres, kinetochore structure, spindle assembly and function, centrosome regulation, various aspects of the cell cycle (metaphase, anaphase), cell cycle progression (kinases, phosphatases, ubiquitin-conjugating enzymes), cell cycle checkpoints and cytokinesis (Tables 1–3).

Since the microarray study was published six years ago,98 recently identified gene sequences related to mitosis and chromosome maintenance have been added to Table 1 to bring the 2002 study up to date.

In summary, persistent upregulation and/or downregulation of key proteins of the division process by deoxycholate, coupled with decreased DNA repair and increased DNA damage, may lead to genomic instability, including mutator phenotypes. Recent studies have indicated that 1) the spindle proteins, Aurora A and BUB1B, are aberrantly expressed in...

Notes: Fold reduction/induction is the ratio of mRNA levels in the deoxycholate-treated cells to the level in the untreated control cells. All fold reduction/induction ratios are the mean of all resistant cell lines HCT-116RB, HCT-116RC, and HCT-116RD compared to long-passage untreated cells and were statistically significant at the 95% probability level (p < 0.05).

dysplastic mucosa of patients with longstanding ulcerative colitis, a pre-neoplastic condition, 2) both Aurora A and BUB1B undergo a shift in subcellular localization during malignant transformation, 3) a reduced level of the spindle checkpoint protein, BUB1B, is associated with aneuploidy in colorectal cancers, and 4) chromatid cohesion defects may underlie chromosome instability in human colorectal cancers. It is an intriguing possibility that these defects occur very early during colon carcinogenesis, and may be caused, in part, by dietary-related factors, such as high levels of endogenous bile acids, coupled with polymorphisms in mitotic checkpoint genes.

Oxidative stress as an important cause of genomic instability

The induction of kinetochore-positive and -negative micronuclei by bile acids may result from aneuploidy (involving the loss and gain of whole chromosomes) or portions of chromosomes, resulting from un repaired double-strand breaks. This bile acid-induced induction of genomic instability is most probably caused by oxidative stress directed at parts of the mitotic machinery, checkpoint proteins and/or direct oxidative damage to DNA that results in double-strand breaks. The only studies that addressed this issue in the gastrointestinal tract are those of Jenkins and colleagues, who evaluated several antioxidants (e.g., vitamin C, resveratrol, EGCG) to determine their effectiveness at reducing deoxycholate-induced micronuclei formation in esophageal cells. Of the antioxidants tested, only vitamin C had a significant effect on reducing micronuclei formation. Since bile acids damage mitochondria, resulting in an increase in mitochondrial ROS, and ROS derived from damaged mitochondria are known to induce genomic instability, various antioxidants specifically directed at mitochondria should be tested for their effectiveness at reducing bile acid-induced genomic instability.

**Notes:** Increase (↑), Decrease (↓), No Change (O).

Since this area of bile acid research is just beginning to be explored, we have reviewed the literature involving other cell types (beyond those of the GI tract) and found that oxidative stress plays a definite role in the induction of genomic instability. Aneuploidy may often reflect defects in mitotic segregation in cancer cells. The faithful cohesion and separation of chromosomes are controlled by a large number of proteins, some of which have a checkpoint function. Increased production of ROS has been reported to induce aneuploidy by impairing the spindle check-point function. The spindle checkpoint is the safeguard mechanism that halts anaphase onset until the mitotic spindle has been assembled and metaphase chromosomes properly attached. At the metaphase-anaphase transition, the APC (anaphase-promoting complex) initiates the separation of sister chromatids by catalyzing the ubiquitination of securin, a protein that prevents the proteolysis of the cohesin complex and the subsequent segregation of the chromosomes, in the securin-separate complex. The APC11 subunit functions as the catalytic core of the APC complex and contains a RING-H2-finger domain, which includes one histidine and seven cysteine residues that coordinate two Zn$^{2+}$ ions. The RING-H2-finger domain is a target of hydrogen peroxide, which induces the release of bound zinc as a result of the oxidation of cysteine residues. The oxidation of APC11 reduces the normal functions of the unoxidized APC11 protein, resulting in the inhibition of ubiquitination and degradation of cyclin B1, and the degradation of securin. Other chromosomal aberrations, such as translocations and dicentric chromosomes, may be caused by accumulation of double-strand breaks induced by oxidative damage, as in Werner syndrome cells. Based on the data from our laboratory that shows the modulation of 71 genes involved in chromosome maintenance, chromatid cohesion, kinetochore-microtubule attachments, chromatid separation, cytokinesis, etc. by deoxycholate (see Tables 1–3), some of these proteins may be oxidatively damaged and/or targeted for destruction by deoxycholate. However, no studies have yet addressed this important mechanism of bile acid-induced damage to dividing cells. Thus, in colon carcinogenesis, the persistent increase in oxidative stress in epithelial cells caused by excessive exposure to bile acids may induce mitotic defects very early in the sequence of events that lead to colon cancer. Hydrophobic bile acids damage mitochondria, and increased levels of oxidative stress caused by defective mitochondria have been proposed as a possible mechanism by which a “mutator phenotype” could arise.

**Bile acids induce ER stress**

The induction of ER stress by hydrophobic bile acids is evidenced by an increase in Gadd153/CHOP, a pro-apoptotic transcription factor, and an increase in GRP78, a molecular chaperone that protects against ER stress. Furthermore, hydrophobic bile acids dilate the cisternae of the endoplasmic reticulum (identified using transmission electron microscopy). The mechanisms by which bile acids cause ER stress probably include the generation of ROS that may damage the ER membrane and/or cause protein unfolding, and the release of Ca$^{2+}$ from the ER through the activation of inositol triphosphate and ryanodine receptors. Excessive ER stress may lead to cell death in the form of apoptosis...

and/or necrosis. Since deoxycholate induces the formation of nitrotyrosine residues in proteins of colon cells,112 ER stress may also be mediated through the generation of RNS.195,201 Persistent ER stress may then select for cells that exhibit activated ER stress-responsive survival pathways important in colon carcinogenesis. We have shown that ER stress-related survival proteins are constitutively upregulated in colon cancer cells that are resistant to deoxycholate-induced apoptosis, and include Grp78,98 S-nitrosylated Grp78114 and S-nitrosylated ORP150,114 another inducible ER stress-related chaperone protein.202 The observed constitutive increase in autophagic proteins98 observed in these resistant cells may also serve to protect against ER stress, although this area of research has not been fully explored.

**Consequences of bile acid-induced mitochondrial damage: metabolic stress, autophagy, apoptosis, and necrosis**

Bile acid-induced DNA damage, ER stress, mitotic stress, and mitochondrial damage may all lead to cell death through various processes including apoptosis, necrosis, autophagic cell death and/or mitotic catastrophe, depending on the level of combined stresses. Of all organelles, mitochondria are most central to the three main cell death pathways, apoptosis, necrosis, and autophagic cell death.201 Apoptosis as a mechanism of mitochondrially-mediated bile acid-induced cell death has been studied the most in cells of the GI tract, as discussed below.

Mitochondria generate most of the ATP used for energy-consuming processes within the cell. Moreover, mitochondria play an important role in the regulation of other cellular processes such as autophagy and apoptosis. Autophagy is a catabolic process involving the degradation of a cell’s own components through the activation of lysosomes. In response to stresses induced by hydrophobic bile acids, autophagy is initiated (unpublished data from our laboratory) as the first mechanism to cope with damage when mitochondrial injury is limited. The damaged mitochondria are sequestered within lysosomes, thereby preventing the release of apoptosis-inducing factors, such as cytochrome c, apoptosis-inducing factor (AIF), and Smac/DIABLO. As more mitochondria are damaged and undergo the mitochondrial membrane permeability transition in response to bile acids, the pro-apoptotic
proteins are released from the mitochondria.\textsuperscript{204} These releases result in the formation of the apoptosome, caspase activation, degradation of vital proteins in the cell and, finally, apoptosis. Apoptosis can be triggered by two distinct signaling cascades, the extrinsic and intrinsic pathways. The extrinsic pathway involves the activation of specific cell surface receptors such as Fas/CD95 and the tumor necrosis factor receptor (TNFR), while the intrinsic pathway is primarily regulated by mitochondria. Importantly, in contrast to hepatocytes and hepatic cancer cell lines, in which hydrophobic bile acids induce apoptosis by an extrinsic pathway, deoxycholate induces apoptosis in colonic epithelial cells in a CD95-independent pathway.\textsuperscript{205} Bile acid-induced mitochondrial damage may initially increase autophagy to rid cells of damaged organelles. As stress continues, apoptosis or autophagic cell death may follow. If, however, the stresses on mitochondria are initially severe, oxidative phosphorylation fails, NAD\textsuperscript{+} levels drop, ATP levels are rapidly depleted, resulting in loss of ionic control,\textsuperscript{206} followed by cell swelling and lysis, characteristic features of necrosis.\textsuperscript{207–211} Apoptotic cell death induced by deoxycholate has been frequently reported in colon epithelial cells.\textsuperscript{41,44,45,98,99,110,112,118,199,205,212–224} Therefore, an understanding of bile acid-induced alterations in mitochondrial function are of great interest. At least two major alterations occur during bile acid-induced mitochondrial dysfunction. These are (1) disruption of electron transport leading to generation of ROS, loss of mitochondrial membrane potential (MMP), decrease in oxidative phosphorylation, and decrease in ATP production, and (2) release of mitochondrial proteins that trigger activation of caspases. Bile acids were shown to be involved in all three processes.

The exact mechanism by which bile acids disrupt electron transport and decrease oxidative phosphorylation has yet to be defined.\textsuperscript{225–227} Experiments performed with mitochondria isolated from hepatocytes clearly demonstrate that hydrophobic bile acids induced perturbations in mitochondrial bioenergetics.\textsuperscript{225,226} Specifically, complex I and complex III of the mitochondrial electron transport chain were inhibited by treatment with10 \textmu M bile acid. Complex IV was inhibited at higher concentrations of bile acids.\textsuperscript{225} The authors speculated that the inhibition of the electron transport complexes may be due to bile acid incorporation into the mitochondrial membranes resulting either in direct toxicity or alteration in lipid composition. When they tested this hypothesis, they found that, indeed, bile acids were incorporated into the mitochondrial membranes. Furthermore, they found that the hydrophobic bile acid, chenodeoxycholic acid, induces alteration in the lipid composition of the mitochondrial membrane, while no alterations were found after treatment with lithocholic acid.\textsuperscript{225} However, it is possible that the changes in lipid composition induced by lithocholic acid were below the limit of detection used in the study.\textsuperscript{225} Membrane structural changes observed using spin-labelling techniques and electron paramagnetic resonance (EPR) spectroscopy analysis also support the involvement of mitochondria in bile acid-induced apoptosis.\textsuperscript{226} These mitochondrial structural changes include modified lipid polarity and fluidity, altered protein order and increased oxidative injury.\textsuperscript{228}

Hydrophobic bile acids cause mitochondrial oxidative stress\textsuperscript{97,110,117,228,229} leading to mitochondrial swelling\textsuperscript{199} and formation of megamitochondria.\textsuperscript{110} The excessive generation of ROS that overwhelms the cells’ antioxidant defenses is most probably responsible for the death of colonic epithelial cells,\textsuperscript{330} and is consistent with the role of oxidative stress in mediating apoptosis in many other types of cells.\textsuperscript{231} Importantly, bile acid-induced apoptosis in HT-29 colon cells is dramatically reduced if mitochondria are protected against ROS by inhibiting complexes I and II of the electron transport chain.\textsuperscript{110} Later studies indicated, moreover, that perturbation of the mitochondrial electron transport chain, in general, and uncoupling of oxidative phosphorylation, attenuates deoxycholate-induced apoptosis.\textsuperscript{199} The mechanism by which this perturbation of mitochondrial function results in apoptosis resistance is not clearly understood. Another effect of hydrophobic bile acids on mitochondria is rapid loss of mitochondrial membrane potential (MMP).\textsuperscript{110,199,205} For example, treatment of SW480 cancer cell line with 0.5 mM deoxycholic acid induced loss of MMP in 5 minutes.\textsuperscript{205} This loss of MMP correlates with the induction of ROS.

The second major effect of hydrophobic bile acids is to induce rapid release of pro-apoptotic proteins in colon cancer cells, such as cytochrome c, which leads to the activation of caspases.\textsuperscript{218} Incubation of HT-29 and HCT-116 colon cells with deoxycholate resulted in the cleavage of procaspases and the activation of effector caspases 2, 3, 7 and 8,\textsuperscript{110,222} while caspase-1 proinflammatory caspase was not cleaved.\textsuperscript{222} Caspases 9 and 3 are rapidly activated by deoxycholate, while caspase 8 activation is a later event.\textsuperscript{110,212,222} Caspase-6 is of particular importance to deoxycholate-induced apoptosis of colon epithelial cells, since the antiapoptotic nitric oxide-targeted enzyme, guanylate cyclase-\textalpha\textsubscript{1}, is specifically cleaved by caspase-6, resulting in apoptosis.\textsuperscript{224} Apoptosis in HCT116 cells is not induced simply by a detergent effect, since sodium dodecyl sulfate (SDS), a detergent that is structurally distinct from bile acids, does not induce apoptosis.\textsuperscript{218} Although protein synthesis inhibitors have been shown to
protect against programmed cell death, *de novo* synthesis of proteins does not appear to be necessary for bile acid-induced apoptosis.218 Altogether, these data suggest that in contrast to the extrinsic induction of apoptosis, as seen in hepatocytes, hydrophobic bile acids primarily activate the intrinsic mitochondrial pathway of apoptosis in colon cancer cell lines.

How exactly do bile acids interact with mitochondria to perturb their function? Hydrophobic bile acids may directly affect mitochondria, leading to disruption of the electron transport chain and increased production of mitochondrial ROS. Alternatively, mitochondria can be damaged indirectly by extramitochondrial ROS produced by plasma membrane bound enzymes targeted by bile acids, such as NAD(P)H oxidase96 (Figure 2). The importance of NAD(P)H to deoxycholate-induced apoptosis was ascertained by the use of an inhibitor of NAD(P)H oxidase, diphenyleneiodonium (DPI).232 DPI attenuated overall ROS production and prevented the occurrence of deoxycholate-induced apoptosis, assessed using translocated membrane phospholipid and nuclei containing condensed chromatin.232 Interestingly, NADPH oxidase levels are elevated in colon cancer cell lines as well as in the tissues from patients with colon cancer.233–236 Another extramitochondrial source of ROS occurs when molecular oxygen is partially reduced during the metabolism of arachidonic acid by the cyclooxygenase (COX) and lipoxygenase (LOX) pathways (Figure 2). Another indirect effect of bile acids on mitochondria is the release of arachidonic acid by the cyclooxygenase (COX) and lipoxygenase (LOX) pathways (Figure 2). Another indirect effect of arachidonic acid by the cyclooxygenase (COX) and lipoxygenase (LOX) pathways (Figure 2). Another indirect effect of arachidonic acid by the cyclooxygenase (COX) and lipoxygenase (LOX) pathways (Figure 2).

Persistent exposure to deoxycholate selects for apoptosis resistance
Repeated long-term exposure of colon epithelial cells to high physiologic concentrations of bile acids may allow preferential survival of cells that are resistant to induction of apoptosis by bile acids. Such apoptosis resistant cells could arise and proliferate by the processes of mutation and Darwinian selection (Figure 3). Apoptosis-resistance in the colon appears to arise in settings where the colonic mucosa is chronically exposed to high physiologic levels of bile acids. Magnuson and colleagues240 reported that chronic feeding of 0.2% cholic acid (added to the AIN-76 diet) to azoxymethane (AOM)-treated Sprague-Dawley rats for 18 weeks resulted in a statistically significant reduction in the number of apoptotic bodies in ACF after an acute low dose of AOM, compared with normal-appearing crypts. Both normal and ACF crypts had fewer apoptotic bodies per 100 cells than crypts from rats fed the control diet.

Work from our laboratory indicated that *in vitro* exposure of apoptosis-sensitive colon epithelial cells (HCT-116) for approximately 40 weeks resulted in the generation of stable apoptosis-resistant cell populations.98 We also evaluated the nonneoplastic flat colonic mucosa of patients in different colon cancer risk groups for apoptosis competence using an ex vivo live cell bioassay.44,45,212,213,241 The apoptosis-inducing agent used in this bioassay was deoxycholate. The nonneoplastic colonic mucosa of patients with colon cancer had a significantly reduced apoptotic index compared to that of low-risk and normal patients. The exact etiologic agents that were responsible for the development of apoptosis resistance are not known, but hydrophobic bile acids, other agents that generate ROS/RNS, and actual components of a high-fat diet may have been key players.

Bile acids, inflammation and colon cancer
Numerous epidemiological studies have shown that fecal bile acid concentrations are increased in populations with a high incidence of colon cancer, suggesting an etiological linkage.242–251 We have shown that supplemental feeding of deoxycholate in a mouse model can cause colitis in association with markers of oxidative stress.115 An important link between high bile acid concentrations and colon cancer may, therefore, be the induction of inflammation, a condition that is associated with many cancers of the GI tract. Bile acids may induce inflammation through a disruption of tight junctions between colonic epithelial cells113 and increase in transepithelial permeability,88 providing a means for entry of pro-inflammatory bacterial species.252 In addition, bile acids may cause dysregulation of cytokine expression through the constitutive activation of NF-κB,98 a redox-associated transcription factor, that contributes to apoptosis resistance and a persistent increase in pro-inflammatory proteins.

Field defects in the colon
A “field defect” or “field of cancerization” is a region of tissue that precedes and predisposes to the development of cancer.253 Field defects are of interest because they provide insight into the early events of progression to cancer and
may lead to clinically useful biomarkers of cancer risk. It is generally considered that a solid tumor is initiated by a series of somatically inherited changes (ie, aneuploidy, mutations or transmissible epigenetic events [epimutations], such as methylation of CpG islands). Aneuploidy, mutations and epimutations are considered to contribute to early progression, usually by causing a somatically inherited proliferative advantage relative to surrounding cells. Furthermore, a mutator phenotype or genetic instability may accelerate the process of mutation followed by Darwinian selection. In a normal population of dividing cells within a tissue, a cell may acquire a proliferative advantage through aneuploidy, mutation or epimutation. Such a cell will tend to undergo clonal expansion and replace neighboring cells, thus giving rise to a patch of abnormal cells. Within this patch, a cell might acquire a second aneuploidy, mutation or epimutation that provides a proliferative advantage compared to other cells within the established patch. This cell may then expand clonally forming a secondary patch within the first patch. Within this new patch, the process of mutation and Darwinian selection may be repeated several more times over a long period, perhaps decades, until a malignant cell arises that clonally expands into a cancer. If solid tumors generally arise by such a process, then tumors should ordinarily be accompanied by a field defect in associated tissue that may appear histologically normal.

The most common type of colorectal cancer, sporadic adenocarcinoma, develops by a pathway that appears to proceed through the following stages: normal flat mucosa, development of fields of defective flat mucosa, aberrant crypt foci, microadenomatous fields, adenoma with low grade dysplasia, adenoma with high grade dysplasia, and adenocarcinoma. However, currently, it is unclear whether all sporadic adenocarcinomas progress through each of these stages.

The morphologically normal appearing colonic mucosa of patients with colorectal neoplasia has been found by proteomic analysis to have numerous changes in protein expression. Alterations of gene expression that occur in the normal appearing colonic mucosa of human colon cancer patients correspond to alterations observed in the normal appearing colonic mucosa of cancer prone APC min mice. The promoter of the DNA repair gene O-methylguanine-DNA methyltransferase (MGMT) is methylated in 46% of colonic tumors. Within this group of tumors with MGMT methylation, 94% of tissue samples from apparently normal mucosa associated with these tumors also had MGMT promoter methylation. Often MGMT methylation was detected as far away as 10 cm from the tumor, indicating a field defect. Also patients with resected adenomas of the colon or rectum had altered expression of O-acetylated sialic acids in their “uninvolved” colon and rectal mucosa compared to sialic acids of colon or rectal mucosa of patients without colon tumors. These findings indicate a field defect of sialic acid expression in the patients with colorectal cancer. Since a decrease in the level of O-acetylated sialic acids on the surface of colon epithelial cells is found to be associated with the early stages of colorectal cancer, it is considered a risk factor. This decrease in the level of O-acetylated sialic acids may lead to an increase in the expression of sialyl LewisX, a tumor-associated antigen related to the progression of colorectal cancer cells to metastasis.

An imbalance of proliferation and apoptosis in the left colon and sigmoid/rectum was found in patients who had a resected large adenoma (≥1.5 cm) compared to patients who never had a tumor. Several lines of evidence indicate that colorectal cancers often arise in a field of apoptosis-resistant cells. The Bcl-xL protein inhibits apoptosis, in part, by inhibiting release of cytochrome c from the mitochondria. The expression of Bcl-xL was found to be increased at 1 cm and 10 cm away from colorectal adenocarcinomas in the non-neoplastic colorectal mucosa, suggesting the presence of an apoptosis-resistant field. The prototypic anti-apoptotic protein, Bcl-2, also behaves similarly. Expression of the antiapoptotic survivin mRNA in colon tumors predicts poor patient survival due to subsequently recurrent colorectal tumors. The normal appearing mucosa of about half of patients with survivin-positive tumors also express this mRNA. This finding suggests that survivin-positive tumors often develop in a normal appearing, but survivin-positive, apoptosis-resistant field. When rats are fed a diet containing 0.2% cholic acid, their colon crypt cells develop increased resistance to apoptosis. Apoptosis-resistant crypts may then spread through the flat colonic mucosa by crypt fission. These various observations suggest that repeated exposure of the colon to high levels of bile acids as a result of a Western style diet cause Darwinian selection for cells resistant to induction of apoptosis, and give rise to fields of apoptosis-resistant epithelium that may further evolve to malignancy.

Work from our laboratory on biomarkers associated with colon cancer risk indicate that, in addition to loss of apoptosis competence, lectin staining using DBA (Dolichos biflorus agglutinin) (a measure of epithelial cell differentiation), cytochrome c oxidase subunit I (CcoI) (a mitochondrial DNA-encoded subunit of CcO) and Pms2 (a DNA repair protein) were all significantly decreased in the normal-appearing flat mucosa of patients with colon cancer compared to that of control subjects.
Scalmati and Lipkin reviewed numerous studies on cell proliferation pattern in patients with colon adenomas or cancer. Expansion of the proliferative compartment (a lumenward displacement of the zone of active cell proliferation in the crypts) occurred along the entire colon of individuals, indicating that there was increased risk throughout the colon, no matter where the actual lesion was located. We also determined that apoptosis resistance in the nonneoplastic flat mucosa of patients with colon cancer was present in several regions of the colon far removed from the tumor site, indicating a generalized field defect of apoptosis resistance, albeit “patchy” in nature, throughout the colon.

A recent study indicated that the consumption of a Western style diet plays a crucial role in the progression of a field defect to colon cancer. Among 1009 patients with resected stage III colon cancer, colon cancer recurred in 324 patients in a median of 5.3 years. This recurrence suggests the frequent presence of a field defect. The patients had all undergone fluorouracil-based adjuvant chemotherapy after surgery, and were evaluated for diet during and 6 months after adjuvant chemotherapy. The rate of cancer recurrence was almost threefold greater among patients in the highest quintile of Western style diet consumption compared to those in the lowest quintile of Western style diet consumption.

Prevention of bile acid-induced stresses and genomic instability: importance of butyrate

We have reviewed evidence that deoxycholate induces cellular stresses in epithelial cells of the GI tract and that bile acids play a role in colon carcinogenesis. Although hydrophobic bile acids were once believed to be mainly tumor promoters, the bile acid induction of DNA damage and aneuploidy indicates that they are also genotoxins relevant to the initiation and progression of the neoplastic process. It is well documented that phytosterols and other types of antioxidants, micronutrients and dietary fiber have antineoplastic effects. An overall discussion of dietary-related colon cancer chemopreventive agents is beyond the scope of this review. However, we will focus on the short-chain fatty acid, butyrate, since previous studies have shown that butyrate interferes with many deleterious effects of hydrophobic bile acids such as increased proliferation, and has been shown to have anti-genotoxic effects on deoxycholate and \( \text{H}_2\text{O}_2 \)-induced genotoxicity in colon epithelial cells. Furthermore, butyrate affects many signal-transduction pathways and histological parameters associated with colon carcinogenesis.

Butyrate is a 4-carbon fatty acid that is an end product of bacterial fermentation of dietary fiber and occurs at concentrations of 2–10 mM in the colon. Certain intestinal bacterial species (eg, \textit{Eubacterium rectale}, \textit{Faecalibacterium prausnitzii}, \textit{Roseburia}, \textit{Coprooccus}) are butyrate producers and beneficial to colon cancer prevention, whereas others, such as \textit{Enterococcus faecalis} (extracellular superoxide and \( \text{H}_2\text{O}_2 \)-producing bacterial species) and \textit{Desulfovibrio} (sulfate-reducing bacteria which produces hydrogen sulfide) are deleterious in that they cause DNA damage and chromosomal instability. In a recent study that quantified specific bacterial species using real-time PCR in the feces of healthy control volunteers and patients with colon cancer, it was found that the butyrate-producing bacteria species were significantly decreased and the superoxide-producing bacterial species were significantly increased in the feces of colon cancer patients compared to control subjects. It is significant that the feces of patients with ulcerative colitis, a pre-neoplastic inflammatory condition of the colon, uniformly contain sulfate-reducing bacteria. Sulfide substantially increases the proliferative index of the crypts in mucosal biopsies, and this increase is prevented by the presence of butyrate. A general consequence of the fermentation of fiber is to reduce the pH of the gut lumen, thereby affecting bacterial metabolism and competition and reducing the bacteria-mediated formation of hydrophobic bile acids. These shifts in bacterial species may be important determinants of the risk of colon cancer.

It is significant that butyrate can protect against oxidative DNA damage induced by deoxycholate \textit{ex vivo} in colono-cytes derived from human biopsies. The processes in the colon that are affected by butyrate include a suppression of proliferation, induction of apoptosis, induction of differentiation, a reduction in inflammation, suppression of NF-\( \kappa \)B activation, increase in xenobiotic metabolizing enzymes and a decrease in DNA damage and genomic instability. All of these processes affect colon carcinogenesis in a profound way.

In our studies of field defects in the human colon, we observed that in the nonneoplastic flat mucosa of patients with colon cancer there is an increase in apoptosis resistance, loss of differentiation, decrease in mitochondrial gene expression (eg, \textit{CcO}) and a decrease in PMS2, a mismatch repair protein. It is significant that butyrate has opposite effects. It can increase differentiation, induce apoptosis, increase \textit{CcO} levels, and has more potent antineoplastic effects on colon cancer cells defective in mismatch repair.
Future directions
We have just begun to understand the role of hydrophobic bile acids in inducing DNA damage and genomic instability in colon epithelial cells, and potential strategies to reduce these deleterious effects. Some key areas that require further experimentation include: 1) the role of oxidative stress as mediators of the effect of bile acids on the reduction of DNA repair proteins (eg, Ku80, MSH3), tumor suppressors (eg, p53) and spindle checkpoint proteins (eg, Mad2); 2) the role of oxidative stress in the deoxycholate-induced induction of micronuclei and aberrant mitoses; 3) the ability of deoxycholate to induce aberrant mitoses and aneuploidy in vivo using mouse models; 4) the possible synergistic effect of bile acids and environmental agents (eg, nicotine from tobacco smoking, arsenic, food carcinogens) in inducing DNA damage and genomic instability; and 5) the effectiveness of dietary-related nutrients and co-factors (eg, zinc, niacin, selenium compounds, plant polyphenols, butyrate) in preventing the genotoxic effects of hydrophobic bile acids both in vitro using cell culture models and in vivo using mouse models. The results from these types of experiments will have relevance to other cancers of the GI tract (esophagus, stomach, liver, pancreas) in which hydrophobic bile acids have a potential etiologic role.

Summary
In this review, we have described the likely major mechanisms by which hydrophobic bile acids can induce stresses on cells, which can then result in colon carcinogenesis. Persistent exposure of colon epithelial cells to hydrophobic bile acids can result in the development of apoptosis resistance and the modulation of numerous genes/proteins associated with chromosomal maintenance and mitosis. Hydrophobic bile acids also damage the genome through multiple mechanisms, including oxidative DNA damage, p53 and other mutations, micronuclei formation and aneuploidy, all major components of genomic instability. These findings link dietary-related factors to the development of genomic instability, extend our understanding of the underlying causes of colon cancer, and may open up new avenues for hypothesis-driven biomarker development to assess colon cancer risk.
