Purpose: Orofacial myofunctional therapy (OMT) is a modality of treatment for children and adults with obstructive sleep apnea (OSA) to promote changes in the musculature of the upper airways. This review summarizes and discusses the effects of OMT on OSA, the therapeutic programs employed, and their possible mechanisms of action.

Methods: We conducted an online literature search using the databases MEDLINE/PubMed, EMBASE, and Web of Science. Search terms were “obstructive sleep apnea” in combination with “myofunctional therapy” OR “oropharyngeal exercises” OR “speech therapy”. We considered original articles in English and Portuguese containing a diagnosis of OSA based on polysomnography (PSG). The primary outcomes of interest for this review were objective measurement derived from PSG and subjective sleep symptoms. The secondary outcome was the evaluation of orofacial myofunctional status.

Results: Eleven studies were included in this review. The studies reviewed reveal that several benefits of OMT were demonstrated in adults, which include significant decrease of apnea–hypopnea index (AHI), reduced arousal index, improvement in subjective symptoms of daytime sleepiness, sleep quality, and life quality. In children with residual apnea, OMT promoted a decrease of AHI, increase in oxygen saturation, and improvement of orofacial myofunctional status. Few of the studies reviewed reported the effects of OMT on the musculature.

Conclusion: The present review showed that OMT is effective for the treatment of adults in reducing the severity of OSA and snoring, and improving the quality of life. OMT is also successful for the treatment of children with residual apnea. In addition, OMT favors the adherence to continuous positive airway pressure. However, randomized and high-quality studies are still rare, and the effects of treatment should also be analyzed on a long-term basis, including measures showing if changes occurred in the musculature.

Keywords: sleep-disordered breathing, myofunctional therapy, oropharyngeal exercises, speech therapy, oral motor exercises

Introduction

Health depends on various factors, with breathing, eating, hydration, and sleep being the primordial among them. However, each of them is susceptible to changes caused by a large number of variables with different degrees of physical and mental consequences. Sleep-disordered breathing (SDB) is a relatively common problem, with obstructive sleep apnea (OSA) being its most severe manifestation.1

OSA is a relevant health problem that involves repeated upper airway collapse during sleep, causing a reduction (hypopnea) or cessation (apnea) of airflow, oxygen desaturation, and fragmented sleep, accompanied by respiratory effort.2,3 Snoring is...
a characteristic signal, but not when it occurs in an isolated
manner. The disease must be diagnosed based on laboratory
full-night polysomnography (PSG), considering that criteria
are different for children younger than 18 years and adults.4

The pathophysiology of OSA during childhood is poorly
known, although adenotonsillar hypertrophy and the instal-
lation of oral breathing are the major factors contributing to
its occurrence.5–9 In general, studies report that the problem
affects 1%–5% of the child population,2 with a peak of inci-
dence among preschoolers, that is, in the age range when
tonsil hypertrophy is more common.10 The consequences of
OSA in children are low school performance, attention deficit
and hyperactivity,11,12 low weight–height development,13 and
cardiovascular dysfunction.2

During adulthood, anatomical and nonanatomical factors
interact and contribute to the manifestation of OSA, such
as narrow pharynx, increased upper airway length, specific
pharyngeal lumen shapes, and collapsible upper airway. The
factors that may play a role in OSA pathogenesis are changes
in the activity of oropharyngeal muscles occurring during
sleep, a poor genioglossus muscle responsiveness to negative
pharyngeal pressure, a low respiratory arousal threshold, and
an oversensitive ventilatory control system.14–18

The disease is more common among men than women and
its prevalence increases with age and in obese persons.17,19
However, menopause is a risk factor for women regardless
of age or body mass index (BMI),20 a factor that tends to
reduce the difference from men, especially when no hormone
replacement therapy is used.21 The symptoms of OSA include
loud snoring, sleep disruption, excessive daytime sleepi-
ness, nocturia,3,22,23 fatigue, morning headache, irritability,
decreased concentration, and memory loss.24

Considered to be a progressive and incapacitating chronic
disease,4 OSA impairs the quality of life and results in comorbiddities such as arterial hypertension, cardiovascular
diseases, and diabetes.25–27 However, the clinical manifesta-
tions are heterogeneous, and if the patients do not present
characteristics such as a high BMI and subjective sleepiness,
the symptoms may also be attributed to comorbid diseases
and OSA will not be investigated and diagnosed.18

The first-line treatment during childhood is adeno-
tonsillectomy, with reported cure or improvement of the
disorder in most cases.9 Orthodontic treatment for correc-
tion of mandibular or maxillomandibular anomalies has
been shown to improve OSA.28 Continuous positive airway
pressure (CPAP) is the treatment of choice for adults with
OSA,20 especially in severe cases, to relieve symptoms and
to reduce the sequelae.18,29 However, mandibular advance-
ment device (MAD), an intraoral dental splint used to pro-
trude the mandible in a forward position during sleep and
thus enlarge the upper airway,30,31 is mainly indicated as the
first-stage treatment of adults with mild-to-moderate OSA
and in severe cases in which attempts with CPAP treatment
fail.20–32 MAD has been considered as a treatment option
for children,33 although it is still under study, and it requires
accurate indication and follow-up due to the craniofacial
growth and development.

Still, surgical interventions are recommended for the cor-
rection of anatomical and morphological problems or as a
second option for adult patients who fail to adhere or respond
to noninvasive treatments. Surgical procedures include uvu-
lopalatopharyngoplasty,34 surgically assisted rapid maxillary
expansion,35 and maxillomandibular advancement.31,36,37

Despite the success rate of these interventions in reduc-
ing apnea–hypopnea index (AHI) and symptoms related
to OSA,20 the need for new or complementary therapeutic
modalities for OSA has been pointed out. The main reasons
for this are the percentage of patients who do not respond satis-
factorily to available treatments, the reduced adherence
to CPAP, especially when the severity of the disease is
moderate,2,18,29 and the possible complications of surgical
procedures, even when limited.2,28,34

The orofacial myofunctional therapy (OMT), or oropha-
ryngeal exercises, with one of the focal points in the promo-
tion of changes in dysfunctional upper airway muscles, was
proposed with success for reducing OSA severity and associ-
ated symptoms in adults.38 Since then, the potential of OMT
has also been investigated to promote reduction of snoring,39
improvement of quality of life,40 and adherence to the use of
CPAP,29 as well to treat residual OSA in children.41 A retro-
spective study summarized the clinical data of children with
OSA and concluded that the OMT after surgery improved
the outcome of treatment.42 Previously, systematic reviews,43
meta-analysis,44,45 and narrative reviews46,47 analyzed the
myofunctional therapy for patients with OSA.

The difference in the current review from the previous
ones is the emphasis on the strategies of therapeutics used by
the various authors and their possible implications regarding
the pathophysiology of OSA, in addition to suggestions for
future investigations.

The objective of the present review is to summarize and
discuss the available literature about OMT for patients with
OSA, the benefits described, the strategies employed, and the
way they can act on the functionality of the upper airway.
Methods

We conducted a bibliographic search up to December 3, 2017, of the following electronic databases: MEDLINE/PubMed, EMBASE, and Web of Science, limited to humans. A manual search of the references of selected studies was conducted as well. Articles in English and Portuguese were accepted. Search terms were “obstructive sleep apnea” in combination with “myofunctional therapy” OR “oropharyngeal exercises” OR “speech therapy”.

Inclusion criteria

Participants

This review was restricted to studies with participants meeting the following criteria: (1) diagnosis of OSA according to the measurement derived from PSG; (2) clinical symptoms of OSA; and (3) no other comorbid conditions (eg, trauma in the head and neck region, cancer, or neurological disease).

Studies

This review included clinical investigations published in journals with peer-review policy, which analyzed the effects of OMT (or oropharyngeal exercises) intervention alone for OSA patients. Randomized studies comparing OMT with a placebo intervention or a controlled intervention and prospective case–control studies were prioritized and mentioned in more detail. However, prospective case series were also included to explore the interventional models, due to the scarcity in relevant publications.

Outcomes of interest

The primary outcomes of interest for this review were objective measurements derived from PSG and subjective sleep symptoms including snoring, daytime sleepiness, and sleep quality. The secondary outcome of interest was the evaluation of orofacial myofunctional status.

Data screening and extraction

The initial screening of the detected documents was conducted blindly in triplicate. The titles were analyzed, as well as the abstract of the publication when available. Articles were selected if at least one reviewer identified them as relevant. A detailed full-text analysis was conducted and two reviewers extracted data from each paper such as study purpose, design, participants, interventions, and main and secondary outcomes. Disagreements regarding data screening and extraction were resolved by consensus among the three reviewers. Twelve questions were elaborated to guide the analyses (Supplementary material) based on a previous study.48

Results

A total of 161 published articles were retrieved from the initial search. After exclusion of duplicates (83) and ineligible studies (67), 11 studies were included. Figure 1 shows a flowchart of the search process used in this review, which is based on PRISMA guidelines for systematic review with the exception that other types of studies were also included here along with randomized controlled trial (RCT) studies.

The types of study included were as follows: RCTs (n=4),29–40 prospective randomized (n=1),41 prospective case–control (n=1),1 and prospective case series (n=5).50–54 Table 1 provides a summary of the reviewed studies.

All RCT studies, with clinical trials registered, analyzed the effect of OMT in young subjects and adults with mild and/or moderate OSA, and the authors were Brazilians.29–40 Two of them included the same sample to answer distinct research questions.29,40 The prospective randomized and prospective case–control studies analyzed the benefits of OMT for children with SDB residual apnea1,41 and the authors were Italians.

OMT

OMT is a treatment modality applied to subjects with orofacial myofunctional disorders (OMDs), that is, with changes in the orofacial structure, in the cervical musculature, or both, which may interfere with the development or functioning of orofacial structures and functions.55 OMT is based on exercises and other strategies that favor sensitivity, proprioception, mobility, coordination, and strength of orofacial structures, as well as promote an appropriate performance of respiration, mastication, deglutition, and speech.

In 1990, the American Speech and Hearing Association first recognized the role of the speech-language pathologist in providing services to persons with OMD, and the knowledge and skills required to evaluate and treat OMD were later described.56 However, the starting point in the development of OMT was the recognition that the correction of malocclusion requires equilibrium of orofacial muscles.57–59 The mutual interest of orthodontists and speech pathologists in oropharyngeal mechanisms led them to cooperate in the study of some associated problems.59 Since then, the range of health problems, treatment strategies,60 and scientific evidence has expanded.

An example of this is that the patients with sequelae of chronic mouth breathing have been long treated by speech-language pathologists61 due to the orofacial myofunctional impairments.62,63 However, the use of PSG for the diagnosis of OSA was not widespread, and therefore, only the symptoms and clinical condition of the patients were considered. Since the last decade, due to the dissemination of knowledge, OSA
has attracted the attention of these professionals. The reason for this interest lies in the fact that orofacial and pharyngeal muscles dysfunction\(^{64}\) and impaired oropharyngeal control are possible contributing factors to airway collapse,\(^{65}\) mainly when associated with an anatomical predisposition.

Therapeutic procedures in this area can be selected based on scientific evidence of benefits of a particular treatment or theoretical solidity when clinical efficacy has not been previously documented.\(^{66}\) Thus, when proposing the first exercise protocol for the reduction of obstructive sleep apnea syndrome (OSAS) severity, Guimarães et al\(^ {38}\) used the scientific reports available about the pathogenesis of OSA and the empirical foundations of speech therapy. According to the authors,\(^ {38}\) the oropharyngeal exercises target soft palate elevation that recruits several upper airway muscles such as the tensor and levator veli palatini, as well as muscle fibers of the palatopharyngeal and palatoglossus muscles, tongue repositioning, and training of mandibular elevation to avoid...
mouth opening. The results obtained in an RCT showed that, after three months of therapy, patients with moderate OSA had a significant reduction of AHI (22.4±4.8 vs 13.7±8.5), an increase of lowest oxygen saturation (83±6 vs 85±7), as well as a reduction of associated symptoms. These changes did not occur in the control (placebo) group.

This protocol was applied in other studies in full or with some modifications in the exercises.39,40 An author added 12 other exercises,53 although giving no reason for this addition. In another study39 whose objective was to treat snoring, the original protocol was simplified to facilitate the incorporation of the training into the daily activities. The number of exercises was reduced to 50% and the duration of each training was set to 8 min. This model was later used for the treatment of OSA.54 Although Baz et al50 have maintained the goals of increasing the tone and endurance of the same muscles for the treatment of OSA, they employed different exercises.

In most of the studies reviewed, the therapeutic program for adults lasted three months, with a weekly visit and training at home for three29,38–40,52 to five times a day. The authors adopted systems of control of adherence to treatment considering the frequency of supervised sessions and a diary indicating home practice. Only one pilot study39 lasted two months, with training at the clinic for 5 min twice a day and four times per week. The strategies and exercises used during therapy are listed in Table 2.

The program applied to children lasted two months, and the exercises included differed from those applied to adults. One study41 involved three meetings with the therapist, the first for evaluation and explanation of the exercises, the second for supervision, and the third for reevaluation, while the other1 involved two monthly meetings. Villa et al31 described the exercises.

**OMT and sleep-breathing variables**

Among the randomized studies that analyzed the effect of OMT on sleep breathing based on full-PSG data, the investigators detected evidence of AHI reduction in adults with moderate OSA,29,38–40 an increased percentage of lowest oxygen saturation (SaO2),38 and a reduction of arousal index (AI).38 In children, the authors observed a decrease of AHI41 and a higher SaO2 after OMT.

Authors of non-randomized studies also reported that, after OMT, patients with mild or moderate OSA showed a significant reduction of AHI50,51,53,54 and AI,50,53,54 and an increase of lowest SaO2 (%)50,51,53,54 compared to baseline. They also observed a decrease in the percentage of the duration of the SaO2 <90.50,53,54 Mohamed et al44 analyzed in parallel the effects of OMT in a group of patients with severe OSA, which showed a decrease in mean AHI, but was not statistically significant. The AHI before and after OMT reported by reviewed authors, as well as the ΔAHI%: (AHI before − AHI after)/AHI before × 100) are summarized in Figure 2.

**OMT and snoring**

A study39 reported a primary efficacy end point of OMT for the objective measurement of snoring in patients with a complaint of snoring and a diagnosis of primary snoring or mild-to-moderate OSA. For this purpose, based on recordings obtained during PSG, the authors established a methodology for the calculation of snore index (total number of snores/total sleep time) and total snore index (sound intensity power generated by all snoring episodes/total sleep time, expressed in arbitrary unit/107). The results showed that OMT promoted a reduction of snoring index (99.5 vs 48.2, p=0.041) and total snore index (60.4 vs 31.0, p=0.041).39 Other authors also reported a reduction of snoring index and episodes of loud snoring.40,54 Additionally, the intensity and frequency of snoring as reported by the bed partner39,52 or as perceived by the patient decreased after the therapy.38,39,53

**OMT and daytime sleepiness, sleep quality, and life quality**

A large number of studies, as noted from the literature as well as observed in the present review, had employed the Epworth Sleepiness Scale (ESS) proposed by Johns67 that evaluates the propensity to sleep in eight different situations, with a total score ranging from zero (absence) to 24 (intense). Although the ESS has been criticized for its sensitivity and specificity and low predictive value, limiting its value in the screening of patients with sleep apnea,68 in almost all papers analyzed, it was used as a measure of the results of treatment regarding daytime sleepiness.

Patients with a mean baseline ESS score ranging from 12±2.6 to 15.4±2.3 showed a significant improvement after OMT, with a mean reduction of six points.29,38,40,50,52,54 However, no change occurred in a group of patients with a median ESS score of 7.0 (3–11) who were, on average, not sleepy or in a group with severe OSA and an ESS score of 20.9±6.2.54

Considering the damage to sleep caused by OSA and its consequences in the daytime and for health in general, other relevant findings were an improved quality of sleep evaluated with the Pittsburg questionnaire58,39 and quality of life.40 The quality of life similarly improved after treatment with OMT alone or combined with CPAP, while no effect was observed in the CPAP-alone group.40 The morning headache symptom was investigated in two studies,50,53 only one of which detected

a reduction from 60% to 20% in the number of patients with this complaint.\textsuperscript{50}

All of these reported data concern the effect of therapy measured immediately after the conclusion of OMT. Only Diaféria et al\textsuperscript{29,40} followed up their patients for three weeks after the end of the intervention and observed that, among

the variables that improved after the OMT, the frequency and intensity of snoring were maintained. Another positive contribution of OMT is that it favors adherence to the use of CPAP.\textsuperscript{29} The educational process and the support received on a weekly basis\textsuperscript{20} during the sessions probably favored greater adherence to CPAP when combined with OMT (65%) than

treatment with CPAP alone (30%).29 Verma et al35 reported differences in response to therapy between men and women. However, the limited number of female participants (n=5) hinders the interpretation.

OMT and orofacial myofunctional status
The efficacy of the OMT for patients with mild–moderate OSA is well characterized by PSG data and questionnaires in the studies analyzed. However, reports about the myofunctional evaluation are limited and not based on a standardized assessment tool that hampers the interpretation and comparison of findings. Only some studies reported the effects promoted by OMT in the oropharyngeal and facial muscles and functions.1,41,51

According to Matsumura et al,52 the percentage of patients with an appropriate pattern of structure and functions, such as lowering of the back of the tongue, high soft palate, suprayoid muscles tonus, nasal breathing, bilateral chewing, and speech, increased in response to the OMT program. An increase in labial closure force resulted from the training specifically applied for this purpose, aiming to promote nasal breathing.51 Diaféria et al29 reported that the Mallampati index improved in the OMT and CPAP+OMT groups and was correlated with the increased strength of the tongue and soft palate, but results of the myofunctional evaluation were not presented.

Villa et al41 used a set of exercises divided into three categories: (1) nasal breathing rehabilitation, (2) labial seal and lip tone exercises, and (3) tongue posture exercises. In a group of children with residual apnea, OMT increased the number of patients with a proper labial seal, lip tone, and nasal breathing.41 In another study conducted on subjects with primary snoring or mild–moderate OSA, there was a significant increase in the objective measures of tongue strength, tongue peak, and endurance. Also, the number of children with oral breathing, abnormal tongue rest position, and lip hypotonia decreased after therapy.1

Future studies would determine whether the effects of OMT in patients with SDB are, in fact, related to improved muscle and orofacial functions.65 For this, validated tools that enable identifying, classifying, and grading changes in muscles and functions status would be used, rather than using dichotomous judgment (yes/no), which only inform the frequency of individuals with normal or altered conditions.

Currently, this is possible with the Orofacial Myofunctional Evaluation with Scores (OMES)-expanded protocol validated for OSA patients.66 The OMES protocol, which is the original version, has also shown to be useful for the characterization of the orofacial myofunctional conditions of children64 and adults with OSA.44 Moreover, objective measures of strength/force51,64 and electromyography64 can contribute to the myofunctional diagnosis and the assessment of the results of the intervention. Therefore, the parameters for the indication of OMT, as well as the benefits of the therapeutic strategies, could be defined appropriately in the future.

Next, based on the literature, we will consider the possible influences of OMT on the oropharyngeal structures. Because many assumptions still need confirmation, this discussion may suggest new ways for further investigations.

Therapeutic strategies and fundamentals
Most of the authors of the papers reviewed adopted a set of exercises for OMT to cover the various oropharyngeal structures,1,38,39,41,50,52–54 that is, tongue, palate, lateral pharyngeal walls, or epiglottis which, separately or in combination, are involved in the collapse of the pharyngeal airway.16,17

Because the increased soft palate length has been associated with higher rates of obstructive apnea, AHI, and respiratory disturbance index,70 to increase the tone of elongated and floppy soft palate and uvula is one of the goals of training.29,38–40,52–54

Exercises focused on the tongue are widely applied, except for a pilot study,11 and are fully justified by the findings related to the pathogenesis of OSA. The dimensions of the tongue (area and volume) are significantly associated with upper airway collapsibility, which in turn is associated with AHI.17 Tongue fat (in mm³) is the main factor explaining the increased tongue volume in patients with OSA compared to controls.71 The possible implications of this finding are the compromised ability of extrinsic muscles to position the tongue and the reduction of the air space in the retroglossal region, where there is a larger percentage of fat in patients with OSA, increasing the risk of sleep apnea.71 Moreover, the genioglossus muscle activity is significantly reduced during rapid eye movement (REM) sleep, especially phasic REM, coincident with the onset of REM hypopnea/obstructive apnea.15

Thus, we should point out the significant reduction of AHI during REM sleep observed after OMT.38 The exercises, as performed during OMT, with a large number of repetitions at a low level of resistance, may promote adaptation of Type I fatigue-resistant muscles, which represent more than half of the muscle fibers in the posterior region of the tongue.66–72

Thus, the training during wakefulness seems to have contributed to the minimization of hypotonia of the genioglossus muscle, the major upper airway dilator muscle, during the most critical phase of sleep when the severity of OSA
worsens. According to a recent review, REM sleep apnea may be more important in mediating insulin resistance and the cardiovascular consequences of OSA.18

The suprahypoid muscles, whose adequacy is also mentioned in some studies as a result of OMT,22–54 include the geniohyoid, stylohyoid, mylohyoid, anterior digastric, and posterior digastric muscles.71 These muscles, together with the styloglossus and genioglossus muscles, participate in specific tasks. For example, “placing the tip of the tongue against the front of the palate and sliding the tongue backward” and “forced tongue sucking upward against the palate, pressing the entire tongue against the palate”.38 These tasks are potentially favorable to an increase in resistance and fatigue threshold of the muscles involved and consequently to reach the goal of appropriate tongue positioning during rest and deglutition.

During the oral phase of deglutition, the surface of the tongue rises, gradually expanding the area of tongue–palate contact from the anterior to the posterior region and compressing the bolus in the direction of the pharynx.74 Elevation of the tongue is promoted by the suprahypoid muscles,75 which also displace the hyoid bone in an anterior direction (geniohyoid) and upper direction (mylohyoid).73,76 Therefore, another result of OMT may be a higher positioning of the hyoid bone, which should also be analyzed in future studies because a lower positioned hyoid bone is a common finding in patients with OSA.17

Mouth breathing during sleep lengthens and narrows the upper airway, which in turn may aggravate OSA severity.71 Presumably, for this reason, Suzuki et al51 decided to train labial closure force to the patients. However, this training alone does not seem to be sufficient to modify the signs and symptoms of apnea since the muscles involved in the collapse of the airways are not directly exercised.

Jaw muscles exercises18,51,53 and training of alternate bilateral mastication and deglutition with teeth in occlusion, focusing on the equilibrium of these functions, have been reported.29,38,52–54 However, no statement was made regarding the fact that not all patients have an occlusal condition to chew alternately on the right and left sides. Moreover, patients with OSA may have associated temporomandibular disorders (TMDs), and a prospective cohort study demonstrated that OSA symptoms preceded first-onset TMD.77

Thus, the goals of rehabilitation of mastication and swallowing should take into account the dynamics relationship between occlusions, muscles, and temporomandibular joint.78 In this sense, there should be bilateral occlusal guides without occlusal interference, especially on the balancing side, as well as muscular coordination to grind the food, to transfer it from one side of the oral cavity to the other, and into the oropharynx. Also, during or after mastication, the patients should not have either joint noise or pain.78

Exercise for buccinator muscles has also been included in various studies.29,38,52–54 It has been recently suggested that the appearance of the cheeks (volume and flaccidity) may be an additional predictor of OSA risk and a visible signal of fat deposition also affecting the tongue and pharynx.69 However, it would be necessary to demonstrate how the type of cheek exercise can favor the muscles related to OSA since their remote location renders improbable a meaningful contribution to remodeling of the oropharyngeal airway.79

The neck circumference, abdominal circumference measures, and BMI are anthropometric predictors of OSA severity.80 Obese patients with a large neck circumference show worse collapsibility of the upper airway.17 Thus, a significant decrease in neck circumference18,39,50,53 correlated with changes in AHI after OMT38,54 indicates that the exercises induced upper airway remodeling.38 Although weight loss is recommended for overweight or obese patients, it is essential to control any variation in BMI when the intention is to analyze the effect of interventions on the severity of OSA, a fact that was not reported in two previous studies.51,54 It should also be pointed out that Verma et al13 emphasized that their experimental design had an advantage over a previous study that did not permit to conclude which set of exercises resulted in maximum benefit for the patients. However, they failed to consider that the effects of training are progressive. Therefore, the highest percentage of improvement of symptoms achieved by patients at the last phase of treatment compared to the previous two does not indicate which set of exercises was most effective.

In summary, the principle of OMT (oropharyngeal exercises) is repetitive muscle training, with specific gains in the coordination, tonicity, and endurance of the muscles, considering the specificity of the exercises adopted (isometric and isometric). The exercises may improve the condition of muscle fatigue in subjects with OSA41 and perhaps act on the equilibrium of contraction between the different muscles that involve the velopharyngeal, oropharyngeal, and hypopharyngeal segments.82 Further, they can decrease the volume of specific structures and fat in the pharynx-dilating muscles, thus also reducing the potential upper airway collapse in apneic subjects. However, these hypotheses have not been verified so far.

As pointed out previously, it needs to be determined whether there is a relationship between tongue exercises and changes in the tongue itself and the palate regarding muscle tone, strength, size, and upper airway volume.44 It
would also be relevant to compare different OMT programs in randomized controlled studies. In addition, whether the therapy results are stable over time remains to be determined; however, this is a hard task, given the difficulty of keeping the participants tied to the research team and of convincing them to submit again to the complex exams.

**Conclusion**

In recent years, OMT for the treatment of patients with OSA has represented a new path in the fight aiming at the minimization or cure of a disease with serious consequences for human beings. The results of randomized studies, although of a limited number, have shown that OMT is effective for the treatment of adult patients with mild and moderate OSA and with primary snoring, and of children with residual apnea. In addition, it provides benefits such as an improved quality of life and increased adherence to CPAP. In general, the goal of the therapy is to induce changes in weak and dysfunctional upper airway muscles, although there is a lack of demonstration based on standardized measures showing whether such changes do occur. New RCTs, including analyses of the effects on the muscles and motor control of the upper airway, could contribute to the dissemination of the indication of OMT for the treatment of OSA.
