Abstract: Anti-inflammatory properties may contribute to the pharmacological effects of angiotensin II receptor blockers (ARBs), a leading therapeutic class in the management of hypertension and related cardiovascular and renal diseases. That possibility, supported by consistent evidence from in-vitro and animal studies showing pro-inflammatory properties of angiotensin II, has been evaluated clinically by measuring the effect of ARBs on C-reactive protein and other circulating indices of inflammation (e-selectin, adhesion molecules, interleukin-6, tissue necrosis factor-alpha, monocyte chemoattractant protein-1) of potential clinical relevance, a body of evidence that this paper aims to review.

Keywords: renin–angiotensin system, angiotensin II type 1 receptor blockers, vascular inflammation, C-reactive protein, circulating inflammatory markers

Introduction
The renin–angiotensin system (RAS; Figure 1) is a multi-step peptidergic system by which circulating angiotensinogen, a liver-derived α-glycoprotein derived from liver and other sources such as the kidney, adipose tissue and the heart, is cleaved by renin, the rate limiting step in the biological cascade, to form the decapetide angiotensin (Ang) I. In turn, AngI is transformed by angiotensin-converting enzyme (ACE), a membrane-bound metalloproteinase expressed in high concentrations on the surface of pulmonary endothelial cells, into the octapeptide AngII, the final effector of the RAS. The endocrine RAS, as above summarized, works in concert with local RASs, ie, self-contained, functionally autonomous AngII-generating systems in the heart, the nervous system, reproductive organs, and in interaction with other biological systems, eg, endothelins or nitric oxide.

Most of the cardiovascular effects of AngII are mediated by G coupled type 1 receptors (AT1Rs) expressed in the vascular wall and organs such as liver, adrenals, brain, lung, kidney and the heart, that coexist with type 2 receptors mediating vasodilation, inhibition of cell growth/proliferation and proapoptosis. (Pro)renin receptors, which accelerate renin catalytic properties, activate circulating prorenin and stimulate AngII-independent intracellular signaling pathways, have recently been identified whose more thorough understanding will likely unveil additional pathophysiologic facets of the RAS as a whole (Figure 2).

Each step of the biological cascade leading to AngII, the biological effector of the system, can be pharmacologically inhibited by renin inhibitors such as aliskiren, ACE inhibitors (ACEIs) and All AT1R blockers (ARBs) (Figure 2), these latter triggering a compensatory renin rise due to the disruption of the feedback inhibition of renin production. The increase in renin activity stimulates the conversion of Ang I and Ang II, which may limit the efficacy of RAS inhibition and the increased renin can also activate the prorenin/renin
A receptor causing renal and cardiovascular damages independent of Ang II (Figure 2). ARBs constitute a heterogeneous pharmacological class (Table 1) sharing AT1R antagonism as a common feature whose clinical profile has been clarified by several published randomized clinical trials (Table 2) in hypertension, cardio-, cerebrovascular disease, diabetes, and others either completed or on their way to completion will further expand our knowledge on this topic.

Although primarily ascribable to AT1R antagonism of the vascular, neurohormonal and renal effects of blood-borne and locally produced AngII, the therapeutic effect of ARBs may be compounded by “pleiotropic” mechanisms related to Ang II-dependent and Ang II-independent pathways.

Angiotensin II type 1 receptor blockers and inflammatory indices in man

Angiotensin II (AngII) is a key player in the pathogenesis of atherosclerotic vascular disease. Acting through the AT1 receptor (AT1R), AngII modulates various cellular processes, including adhesion, migration, and proliferation. This biochemical profile suggests that AngII acts as a potent inflammatory mediator, contributing to the development and progression of atherosclerosis.

The classical view of atherosclerosis as a lesion composed of lipid deposits has been replaced by a chronic inflammatory disorder. This perspective is supported by evidence showing that AngII plays a role in the activation and recruitment of immune cells to the site of inflammation. Through the expression of chemokines and adhesion molecules, AngII facilitates the infiltration of monocytes/macrophages and leukocytes into the vascular wall, contributing to the formation of atherosclerotic plaques.

AngII binds to AT1R on vascular endothelial cells, stimulating the expression of adhesion molecules such as P- and E-selectin, which capture free-flowing leukocytes from the blood, allowing them to roll and then adhere to the endothelium. This process is followed by the expression of intercellular (ICAM-1) and vascular (VCAM-1) adhesion molecules, enabling leukocytes to accumulate at sites of inflammation and infiltrate the endothelial layer via the release of chemokines like monocyte chemoattractant protein-1 (MCP-1). Additionally, AngII stimulates the expression of cytokines such as interleukin-6 (IL-6), which activates macrophages and further amplifies the inflammatory response.

Platelet binding to endothelial cells also contributes to thrombin release, a key factor in the formation of atherosclerotic plaques. AngII stimulates platelet binding to endothelial cells, resulting in the release of pro-inflammatory mediators, including thrombin.

The modulation of the multifactorial effects of AngII on vascular cells (Figure 3) by which the peptide may accelerate the onset and progression of atherosclerotic vascular disease is supported by growing evidence. This evidence demonstrates the cytokine-like potential of locally-synthesized AngII to act in a paracrine, autocrine, and possibly intracrine manner to promote vascular inflammation, a main component of the atherogenic process. This possibility has led to a series of in-vitro and animal studies that have stimulated a number of clinical studies focusing on the effect of AngII on circulating inflammatory indices.

The significance of this relationship is further underscored by the observed association between circulating inflammatory markers and cardiovascular outcomes. Elevated levels of inflammatory cytokines are linked to an increased risk of cardiovascular events in patients with atherosclerotic vascular disease.

and multiform (Figure 3) and involve several intracellular pathways leading to inflammation and proliferation reviewed in detail elsewhere.33,79

Ang II directly act on NAD(P)H oxidase, an enzyme present in vascular wall cells consisting of membrane and cytoplasmic subunits and a small GTP-binding protein Rac.81 NAD(P)H oxidase generates reactive oxygen species (ROS) that activate nuclear factor kappa B (NFkB), a transcription factor binding specific sequences in the promoter regions of target genes thus inducing transcription of proinflammatory cytokines, chemokines, mediators of inflammation, immune receptors, and adhesion molecules.82 The effect of AngII on NFkB has been documented in endothelial and vascular smooth muscle, glomerular, tubular, and mononuclear cells and its overactivation in tissue of ANGII stimulated animals related to AT1R activation.81 ROS excess also impairs endothelial function by decreasing NO bioavailability by both constitutive (eNOS) and inducible (iNOS) NO synthases, accelerates atherogenesis83 and attenuates BP raise in response to AngII infusion,84,85 a piece of evidence suggestive of a role of inflammatory components in the genesis of essential hypertension.

The effect of ARBs on circulating inflammatory indices

ARBs and C-reactive protein

C-reactive protein (CRP) is a protein synthesized by hepatocytes under the influence of IL-6 within 24–72 hrs after infectious and noninfectious disorders, including myocardial infarction and other acute coronary syndromes. Detection of both CRP mRNA and protein in vascular smooth muscle cells and macrophages within atherosclerotic plaques suggests its de novo synthesis in the vessel wall in which CRP may activate the complement system and/or interact with macrophages and other resident vascular cells.86 Due to its long-term stability during storage, long half-life, lack of diurnal variation as well as lack of age and sex dependence, circulating CRP represents a reliable long-term index of subclinical inflammation provided of predictive power for cardiovascular events in patients with both established coronary artery disease and in primary prevention independent of concomitant factors such as smoking status, diabetes, blood pressure, use of hormone-replacement therapy and low-density lipoprotein (LDL) cholesterol.87

Because of those favorable characteristics for risk stratification, several studies listed in Table 3 have addressed the effect of ARBs on circulating CRP levels in hypertensive and diabetic patients. The Val-MARC (Valsartan-Managing blood pressure Aggressively and evaluating Reductions in hsCRP) study is probably the more important trial addressing the issue of whether BP reduction per se lowers CRP levels, or whether selective AT1R antagonism through valsartan may have independent effects to reduce CRP levels.89 The study included 1668 patients with stage 2 hypertension randomly allocated to either valsartan alone (160–320 mg/day, n = 836) or valsartan/hydrochlorothiazide (HCTZ, 160–320 mg/12.5 mg/day, n = 832) for a period of six weeks. At the end of treatment, valsartan

alone slightly but significantly reduced high sensitivity (hs)CRP levels, an effect maintained over an extended follow-up period albeit with a low level of association with achieved BP. As CRP levels were unchanged in the combined valsartan/HCTZ therapy group, the data were taken as suggestive of a negative interaction of thiazide diuretics with the anti-inflammatory effects of ARBs conclusion. That conclusion contrasts, though, with the results of the VAST (Valsartan/HCTZ versus Amlodipine in STage II hypertensive patients) trial whose primary objective was to determine whether valsartan 160 mg plus HCTZ 25 mg OD would be more effective than monotherapy with amlodipine 10 mg OD. Modulation by valsartan of CRP levels was confirmed in other, small-sized studies in patients with hypertension,<sup>55</sup> congestive heart failure<sup>96</sup> as well as normal subjects<sup>85</sup> although other reports did not confirm those data.<sup>58,73,77</sup> For example, Rajagopalan and colleagues<sup>73</sup> found no significant change in hs-CRP in 104 hypertensive patients randomized to 12 weeks valsartan (160 mg daily) as compared with significant reductions in those on combined statin treatment. Galle and colleagues in the VIVALDI trial (investigate the efficacy of telmisartan versus VALsartan in hypertensive type 2 Diabetic patients with overt nephropathy)<sup>77</sup> found no influence of valsartan (160 mg) as well as telmisartan (80 mg) on inflammatory parameters in 255 hypertensive patients with diabetic nephropathy and the study was unable to show any effect beyond that due to blood pressure.
control. Nonsignificant changes in hsCRP were reported with candesartan, including the CENTRO (CandesarT on aTherogenic Risk factors) trial, a multicenter, randomized, double blind comparison of candesartan and enalapril, an ACEI, in hypertensive, diabetic patients showing no effect of the ARB (but also enalapril) on hsCRP. Similar discrepancies also characterized the effect of telmisartan, including the already commented VIVALDI trial. Positive results were reported for irbesartan in two studies in coronary heart disease patients, but their small sample size preludes generalization. Olmesartan was tested in a well designed and carefully conducted prospective, placebo-controlled, double-blind multicenter study by Fliser and colleagues who measured hs-CRP levels and other inflammatory markers in 199 patients with essential hypertension and obesity-related microinflammation. After 12 weeks of therapy, with additional HTCZ if needed, olmesartan decreased hs-CRP (−21.1%; P < 0.02), TNF-α (−13.6%; P < 0.01), IL-6 (−18.0%; P < 0.01) and MCP-1 (−6.5%; P < 0.01). Albeit gathered in a well designed and carefully conducted study, those results need confirmation in additional trials, however. A greater anti-inflammatory effect of olmesartan as compared with telmisartan was recently claimed by Nakayama and colleagues, but the conclusion is flawed by the experimental design lacking adequate washout prior to randomization. Notably, losartan did not affect CRP in patients with diabetic nephropathy, coronary artery disease, and hypertension. No data are available about the effect of eprosartan.

**ARBs and circulating adhesion molecules, cytokines, and chemokines**

A number of clinical studies have assessed the effect of ARBs on circulating inflammatory markers other than CRP such as E-selectin, a member of the selectin family expressed on the surface of stimulated endothelial cells, and ICAM-1 and VCAM-1, two immunoglobulin-like molecules acting as endothelial ligands to facilitate endothelial adhesion of circulating leukocytes. Those biological products circulate in blood as a result of enzymatic cleavage or from shedding of damaged or activated endothelial cells under the influence of proatherogenic stimuli such as hypertension, type 2 diabetes, obesity as well as established peripheral and coronary artery disease. While the prognostic power of raised s-eSEL is dubious, circulating ICAM-1 predicted cardiovascular risk independent of traditional risk factors in the 14,916 healthy men enrolled in the Physicians’ Health Study (PHS), as well as in the elderly, apparently healthy subjects of the Atherosclerosis Risk in Communities (ARIC) study. On the other hand, VCAM-1 did not predict future cardiovascular risk, suggesting important distinctions between the roles of different CAMs in atherogenesis. Evidence has also been gathered in support of the clinical relevance of inflammatory cytokines such as circulating IL-6 and TNF-α, and MCP-1, a chemokine that orchestrates the migration of leukocytes into the intima and within atherosclerotic lesions. Increased plasma IL-6 levels were reported early after admission for acute coronary syndromes and associated with a complicated in-hospital course and higher IL-6 levels predicted acute coronary syndromes in apparently healthy men. Post-MI elevations of circulating TNF-α and MCP-1 also associated with an increased risk of recurrent coronary events.

As summarized in Table 4, losartan did not affect circulating adhesion molecules in patients with diabetes and/or hypertension and/or coronary artery disease while a significant decrease was reported only in two, small studies in normal subjects. The effect of the drug on eSEL, on the other hand, was consistently negative. The same discrepant behavior was shared by candesartan, the other ARBs frequently used in studies of this kind, while either eprosartan or telmisartan treatment did not change VCAM-1 levels to a statistically significant extent. No data are available for irbesartan or olmesartan.

As shown in Table 4, similar considerations hold for the effect of ARBs on MCP-1, TNF-α and IL-6.

**Conclusions**

Despite a quite consistent evidence from basic research field, the anti-inflammatory effect of ARBs in man, at least to the extent derived from their effect on circulating inflammatory indices, is quite inconsistent, a conclusion that applies even to studies apparently adopting the same drug at similar dosages, comparable patient selection criteria and experimental design. Further limitations derive from the small sample sizes that characterize many of the available studies, heterogeneity of ARBs as a pharmacological class (see Table 1), lack of prospective studies evaluating the relationship between anti-inflammatory effects of ARBs and incident morbid events and the complexity of the effects of AngII on vascular biology (Figure 3). Additional difficulties derive from the inherent variability of circulating inflammatory indices, a pattern emerging quite clearly from Table 3 to which genetic factors acting at the individual level may contribute. Not unlike ARBs, ACEIs showed divergent results, sometimes in contrast with the effects of the ARBs. Thus, enalapril but not losartan reduced inflammatory markers in hypertensive and diabetic patients.
It should also be noted that interference on inflammatory indices is not specific for RAS inhibitors since other classes of cardiovascular drugs such as beta-adrenoceptor blocking drugs,\textsuperscript{77,78} statins\textsuperscript{79} as well as nonpharmacological interventions such as exercise training, weight loss\textsuperscript{80} and nutritional factors\textsuperscript{100} may influence CRP levels. Suggestions have also been raised about a beneficial effect of intensive blood pressure and lipid treatment \emph{per se}.\textsuperscript{101} Moreover, the validity of circulating inflammatory markers as a surrogate end-point for an underlying inflammatory process is unclear since the relationship with their activity at the local level is unknown. Importantly, modifications in circulating CRP, even when highly consistent such as in the case of statins,\textsuperscript{79} have dubious pathophysiological significance since decrements in hsCRP were associated with either no change,\textsuperscript{102,103} or improved cardiovascular prognosis.\textsuperscript{104} As a matter of fact, the LDL- and CRP-lowering effect of statins\textsuperscript{90,105} are closely intertwined, possibly as an expression of their metabolic effect on the liver. For these reasons, no firm conclusions can be drawn about their effect at this point and further studies are needed.
