Objectives: Few studies on prognostic indicators for primary thyroid lymphoma (PTL) have been presented due to the uncommon nature of the tumor. This is the first study to explore the independent prognostic factors in the 2 PTL subtypes.

Methods: We retrospectively reviewed 1,653 cases of PTL. The cases comprised 28 Chinese patients from a local cohort and 1,625 patients from the Surveillance, Epidemiology, and End Results database from 1973 to 2013. Statistical analysis was performed to determine the demographics and prognostic factors of PTL patients.

Results: The disease-specific survival (DSS) and prognostic indicators were significantly different between patients with extranodal marginal zone B-cell lymphoma of the mucosa-associated lymphoid tissue (MALT) and patients with diffuse large B-cell lymphoma (DLBCL). Patients with MALT lymphoma were younger ($P=0.011$) and had lower clinical stage ($P=0.014$) compared to patients with DLBCL. Cox regression analysis revealed that age, treatment modalities employed, clinical stage, and number of other types of cancer were independent prognostic factors for DLBCL patients.

Conclusion: PTL demonstrates specific clinical features and is associated with a relatively good prognosis. Older age is associated with poor DSS in both MALT patients and DLBCL patients. Additionally, combination of different treatment modalities is associated with improved DSS in DLBCL patients.

Keywords: primary thyroid lymphoma, SEER database, disease-specific survival, combined modality treatment, prognosis

Introduction

Lymphoma is one of the most common types of malignancy in human beings, which often develops into extranodal lymphoma in certain organs and tissues, such as in the gastrointestinal tract and on the skin.¹ Primary thyroid lymphoma (PTL) is a rare type of extranodal lymphoma, which is defined as lymphoma that involves only the thyroid or the thyroid and regional nodes without metastasis to other areas at the time of diagnosis.² PTL, most of which are non-Hodgkin's lymphoma (NHL) of B-cell origin, accounts for approximately 1%–5% of thyroid malignancies and 2% of all extranodal lymphomas. PTL predominantly affects elderly female patients, who are older than 70 years. Lymphocytic thyroiditis may be involved in the development of PTL by allowing lymphoid cell infiltration of the thyroid bed.³ The common histological

subtypes are extranodal marginal zone B-cell lymphoma of the mucosa-associated lymphoid tissue (MALT) and diffuse large B-cell lymphoma (DLBCL).

Constructing a database, which includes the information of patients with PTL, for the evaluation of possible prognostic factors and optimal treatment modalities is difficult due to the rarity of the condition. A few studies have discussed the potential pathologic predictors of survival for PTL.^{4,5} However, the prognostic factors between PTL subtypes, such MALT and DLBCL, have yet to be explored.

The present study aims to review and analyze the outcome of patients treated with PTL at the 2 affiliated hospitals of Wenzhou Medical University. The study also aims to discover potential associations among patient demographics, pathologic features, and clinical characteristics in different PTL subtypes using the Surveillance, Epidemiology, and End Results (SEER) database.

Patients and methods

Patient characteristics

From 2005 to 2017, 28 patients with PTL who underwent treatments at the 2 affiliated hospitals of Wenzhou Medical University were identified and evaluated. The mean age at diagnosis was 59 years, with 79% of the patients being female. Moreover, men were younger than women at the age of diagnosis (40 vs 64 years, respectively, $P=0.003$). Routine ultrasonography detected PTL as thyroid nodules in 26 out of 28 patients (92.8%). Preoperative peripheral blood count and biochemical tests were almost within the normal range. All samples were reviewed retrospectively by 2 pathologists to confirm histological diagnosis. All patients had histologic verification of PTL, either from a needle biopsy ($n=2$) or by surgery ($n=26$). Immunohistochemical tests showed an abnormal increase in Ki-67 in most of the patients (Table 1 provides additional details and information). Furthermore, the Ann Arbor system was used to stage these patients. The

patients whose samples were used had provided written informed consent for their use in future research.

Characteristics qualifying patients for surgical procedures are as follows:

1. Rapidly growing thyroid tumor with compression symptoms involving the trachea and adjacent structures.
2. The tumor cannot be diagnosed by preoperative examinations and biopsy.
3. Patient strongly demands surgical procedure.

Characteristics of qualifying patients for combined treatment are as follows:

1. Rapidly growing thyroid tumor with compressive symptoms involving the trachea and adjacent structures.
2. The tumor cannot be diagnosed by preoperative examinations and biopsy.
3. Aggressive PTL subtypes confirmed by postoperative immunohistochemical diagnosis.
4. Patients with advanced clinical stage.
5. Patient provides permission for combined treatment.

The SEER 18 database between 1973 and 2013 was utilized to analyze the frequency, treatment, and survival information for patients with PTL. The database comprises approximately 28% of the US population. The coding system of the International Classification of Diseases for Oncology, Third Edition (ICD-O-3), was used to select patients from the SEER database with primary tumors originating in the thyroid (ICD-O-3 code C73.9), and histology-specific codes (ICD-O-3 codes 9590–9758) were then used to identify those with PTL. A total of 1,625 patients with PTL were identified in the SEER 18 database from 1973 to 2013. Clinical and pathological variables (eg, age, gender, and marital status; tumor stage, differentiation, and number of other types of cancer; and treatment modalities employed) were analyzed. The SEER database does not contain any identifying patient information.

Ethical approval for this study was obtained from the ethical committee of the two affiliated hospitals of Wenzhou Medical University. Written informed consent was obtained from all of the local cohort participants.

Treatments

In the local cohort, almost all of the patients who came to our hospital sought medical assistance due to rapidly enlarging thyroid nodules with a varying extent of dyspnea. Most patients with PTL had been treated with surgery (n=26, 92.9%); the other 2 patients had surgical contraindications and refused surgery. Twelve patients (42.9%) had chemotherapy

as individualized postoperative treatment, which consisted of rituximab, cyclophosphamide, doxorubicin, vincristine, and prednisone (RCHOP regimen). Generally, 4 to 8 cycles of chemotherapy were administered at 3-week intervals. Treatment-related toxicity was not documented in any patients. In the SEER cohort, 901 (55.4%) patients with PTL underwent surgery treatment and 858 (52.8%) patients underwent radiotherapy. Individualized treatment included surgery alone (n=472, 29.1%), radiotherapy alone (n=429, 26.4%), or combined surgery and radiotherapy (n=429, 26.4%).

Statistical analysis

The Kaplan–Meier method and log-rank tests were used to determine disease-specific survival (DSS). The Cox regression analysis was performed to evaluate the prognostic factors of patients with PTL. SPSS software (version 18.0, SPSS Inc., Chicago, IL, USA) was used for all statistical analysis. All *P*-values were 2 sided, and a *P*-value of <0.05 was considered statistically significant.

Results

Follow-up data of local cohort

The sample of 28 patients included 6 men (21.4%) and 22 women (78.6%), with a male-to-female ratio of 0.27. Age range was 15–85 (mean, 59 years), and the median DSS was 31 months (range, 0–131 months). In 26 out of the 28 patients (92.8%), PTL was detected as thyroid nodules during a routine examination. Conversely, only 2 of the patients (7.2%) presented lymphoma-associated symptom, such as night sweat (Table 1). PTL patients who underwent surgery alone (median DSS, 52.2 months) or combined treatment (median DSS, 42.4 months) showed a longer DSS compared with patients who underwent no treatment (median DSS, 0.5 months). However, the finding was not statistically significant ($P>0.05$). The DSS between the 2 treatment groups was not statistically different ($P>0.05$). Most of the patients were in early stages of PTL (26/28). Patients with MALT and DLBCL accounted for the majority of all patients (82.1%). Between these 2 subtypes of PTL, patients with MALT showed a tendency of younger age at presentation ($P=0.011$), lower clinical stage ($P=0.014$), and longer median DSS compared with patients with DLBCL (Table 2). An independent prognostic factor was not found due to limited case counts.

Relationship between PTL subtypes and clinicopathological features

The relationship between MALT and DLBCL groups from the SEER cohort was investigated (Table 3). The results revealed that younger age ($P<0.001$) and lower clinical stage

($P<0.001$) were significantly related to the MALT subtype. Moreover, surgeons were more likely to select surgery alone ($P<0.001$) or its combination with radiation ($P<0.001$) for patients with MALT. Specifically, more aggressive surgical treatments were performed on MALT patients ($P<0.001$). With regard to medical history, patients with MALT more often suffered from other types of cancer ($P<0.001$). Moreover, race ($P<0.001$) and geographic region ($P<0.001$) were markedly different among the 2 groups. No significant associations were observed between the 2 PTL subtypes and gender, marital status, and mean survival months ($P>0.05$).

Relationship between DSS rate and clinicopathological features among different PTL subtypes

Further exploration was performed to study the association between DSS rate and clinicopathological features among

For personal use only.

of cancer, and treatment modalities employed had no effect on the DSS of patients with MALT ($P>0.05$). However, in the DLBCL group, lower DSS rate was associated with older age ($P<0.001$; Figure 1C), clinical stage of IV ($P=0.009$; Figure 1D), unmarried status ($P<0.001$; Figure 1E), residence in the northern region ($P=0.031$; Figure 1F), and presence of a single lymphoma ($P<0.05$; Figure 1G). In comparison with patients who accepted no treatment, surgery alone ($P=0.018$) or combined surgery and radiotherapy ($P=0.006$) could markedly improve the DSS rate of patients with DLBCL in terms of the treatment modalities employed (Figure 1H). Specifically, aggressive surgical treatments, including thyroid lobectomy ($P=0.014$) and near-total/total thyroidectomy ($P=0.019$), could significantly prolong the DSS of patients with DLBCL (Figure 1I). Gender and race did not affect the DSS of patients with PTL in either groups ($P>0.05$).

Prognostic factors analysis for different PTL subtypes

The Cox regression analysis was also conducted to assess the prognostic factors of patients with MALT and DLBCL according to the follow-up data from the SEER database. Neither univariate nor multivariate Cox regression analysis could determine the proper prognostic factors from the aforementioned clinical features because of the relatively low mortality rate (14/258, 5.4%) of patients with MALT. In the DLBCL group, the univariate Cox regression analysis (Table 4) determined that older age (hazard ratio [HR] =3.5, 95% confidence interval [CI] =2.019–6.069, $P<0.001$), clinical stage of IV (HR =1.918, 95% CI =1.163–3.161, $P=0.011$), unmarried status (HR =1.751, 95% CI =1.288–2.380, $P<0.001$), and residence in northern region (HR =1.494, 95% CI = 1.031–2.165, $P=0.034$) were significantly associated with poor prognosis for patients with DLBCL. Surgery alone (HR =0.547, 95% CI =0.348–0.859, $P=0.009$) or combined surgery and radiotherapy (HR =0.491, 95% CI =0.314–0.769, $P=0.002$) was also found to improve the DSS of DLBCL patients effectively. Aggressive surgical treatments, including thyroid lobectomy (HR =0.57, 95% CI =0.361–0.900, $P=0.016$) and near-total/total thyroidectomy (HR =0.597, 95% CI =0.384–0.929, $P=0.022$), were associated with better prognosis for these patients. Patients with DLBCL with another type of cancer (HR =0.237, 95% CI =0.142–0.397, $P<0.001$) could be a protective factor of DSS. Further multivariate Cox regression analysis revealed that age (HR =3.750, 95% CI =2.057–6.838, $P<0.001$), treatment modalities employed (HR =0.821, 95% CI =0.702–0.961, $P=0.014$), clinical stage (HR =1.203, 95% CI =1.021–1.418,

$P=0.027$), and number of other types of cancer (HR =0.205, 95% CI =0.116–0.360, $P<0.001$) were independent prognostic factors (Table 5).

Discussion

PTL is a rare condition, with an estimated incidence of less than 5% of thyroid malignancies and approximately 2% extranodal lymphomas.² Histologically, the majority of PTL is NHL, which originated from B-cell lineage.⁶ Most patients with PTL had DLBCL, whereas approximately

Table 5 Multivariate Cox regression analysis for DLBCL patients in the SEER cohort

one-third of patients were found to have MALT.⁷ Prognosis varied with different PTL subtypes. Patients with MALT show better prognosis due to its more indolent behavior and more favorable response to therapy compared with DLBCL patients. However, the prognostic values of clinical features and treatment modalities employed in the 2 subtypes remain unknown. To the best of the authors' knowledge, this study is the first to explore the independent prognostic factors between the 2 different PTL subtypes.

In this study, we performed a retrospective analysis involving 28 patients and used statistical tools to analyze clinical data. Collectively, the results demonstrated that patients with PTL may benefit from both surgical procedures and combined treatments. Meanwhile, patients with MALT tended to be younger, have lower clinical stage, and have longer median DSS compared with DLBCL patients.

To avoid the discrepancies in the related prevalence of histologic subtypes, DSS, and independent prognostic factors caused by the limited case counts,^{5,8} the clinical features of the local cohort were initially compared with the SEER cohort, and no significant difference was found between the 2 cohorts (data not shown). Prior studies have found that approximately 90% of patients have early-stage PTL,^{9–11} which is similar to the present study (92.8%, 26/28). DLBCL is universally considered as the most common subtype of PTL.^{2,12,13} However, in our study, DLBCL only accounted for 35.7% (10/28) of all PTL, which is considerably different from the rate reported previously. MALT, the major subtype of the present study, accounted for 46.4% (13/28) of all patients, which is higher than previously reported rates of 20%–40%.^{9,14} Further analysis of the local cohort revealed that significant differences were found in diagnostic age, clinical stage, and median DSS between the MALT and DLBCL groups, which was further confirmed by the SEER cohort analysis.

Although various treatments, such as surgery, chemotherapy, and radiotherapy, have been applied alone or in combination to cure PTL, no clear guidelines for therapy

have emerged. Surgery that constitutes the foundation of treating rapidly growing thyroid tumors, including adenomas, at present plays only a marginal role limited to immediate interventions associated with compression symptoms involving the trachea and adjacent structures and is a significant element of palliative surgical management that ensures the patency of the respiratory tract prior to initiation of irradiation therapy. At present, the role of surgical treatment in PTL remains controversial. Some studies contended that surgery favorably influenced the outcome in patients with PTL in certain small case series.^{9,15} Derringer et al⁹ reported that 16 patients with MALT, who were only treated with surgery, reached a 100% overall survival (OS) rate after a 7-year follow-up. However, a study conducted by Mayo Clinic¹⁶ revealed that the combination of total thyroidectomy with adjuvant radiotherapy could not improve the long-term outcome compared with biopsy associated with radiotherapy in early stages. In the present study, almost all patients (26/28) initially underwent surgical treatment due to the dyspnea caused by the rapidly enlarging neck mass. The MALT group showed higher surgical rate (13/13) than the DLBCL group (8/10), and more aggressive surgical treatments were performed on patients with MALT. Patients with MALT treated with surgery alone or in combination with chemotherapy also achieved a 100% DSS in this study (13/13). Moreover, 37.5% (3/8) of patients with DLBCL suffered from PTL recurrence within 3 years after their treatments. Analysis of the SEER cohort also validated that higher surgical rate and more complex treatment regimens were correlated with patients with MALT. In the SEER cohort, surgical treatment alone or in combination with radiotherapy could effectively improve the DSS of patients with DLBCL. In patients with MALT, surgical treatment alone cannot affect either OS or DSS of patients with MALT. However, surgical treatment, when combined with radiotherapy, significantly improved the OS of MALT patients.

Over the last several years, chemotherapy alone or in combination with radiation has become the primary treatment for PTL.^{17–19} Combined chemotherapy regimen, especially the RCHOP scheme, was the most common choice for NHL treatment.^{20,21} Most of the PTL subtypes were recommended to be treated by the combination of chemotherapy and radiotherapy even at early stages.²² Watanabe et al²³ revealed that long-term outcomes of localized thyroid MALT lymphoma are favorable with combined treatment modalities. Cha et al²⁴ found that radiotherapy alone for MALT and chemotherapy followed by radiotherapy for high-grade lymphoma can be effective treatment options for PTL. Mian et al²⁵ reported

that patients with DLBCL who underwent chemotherapy followed by radiotherapy had a statistically significantly longer progression-free survival time than those who received a single therapy. A literature review that included 211 patients conducted by Doria et al²⁶ suggested that chemotherapy combined with radiation therapy could lower distant and overall recurrence rates compared with radiotherapy alone (overall recurrence 8% vs 37%; distant recurrence 5% vs 31%). Moreover, Fuller et al²⁷ reported that higher doses of radiotherapy combined with chemotherapy could lead to achievement of better local control for patients with DLBCL. The use of radiotherapy alone to cure PTL was uncommon, and only a few cases have reported that the sole use of radiotherapy could lead to a favorable prognosis for patients with MALT.^{15,28} Although insignificant, the present study revealed that patients in the local cohort who received surgical treatment combined with chemotherapy (RCHOP regimen) had a lower recurrence rate (8% vs 21%) compared with surgical treatment alone. With a large number of patients, a different significant conclusion may have been reached. These findings suggested that local therapy of PTL alone was insufficient to cure diseases and combined systemic treatments may be warranted.

PTL prognosis heavily depends on the clinical stage.²⁹ Previous studies have found that OS from PTL ranges from 56% to 90%.^{5,14} The patients with stage-I PTL have the best prognosis. The 5-year DSS for stage-I has been reported to be as high as 100% in certain case series.^{9,30} However, the 5-year DSS can dramatically decrease from 90% to 35% when the intrathyroidal disease becomes an extrathyroidal disease. In the current study, none of patients with stage-I PTL died during the follow-up, which was consistent with previous reports. In the SEER cohort, the 5-year OS and DSS for patients with stage-I PTL were 76.5% and 87.2%, respectively, which was also within the range reported previously. The prognosis of PTL also varied from different histological classifications.²⁹ Indolent subtypes, such as MALT, were commonly acknowledged to have a better prognosis than aggressive subtypes due to their relatively mild/benign behaviors and more positive response to therapy. The analysis of the SEER database also confirmed this finding. According to the follow-up data, the 5-year OS and DSS for patients with MALT reached 84.4% and 96.1%, respectively. Meanwhile, the 5-year OS and DSS for patients with DLBCL were 66.4% and 81.3%, respectively, which was significantly lower than that of patients with MALT. Further analysis suggested that older age (>55 years) was negatively correlated with prognosis for patients

with MALT and DLBCL. In addition, lower clinical stage, and multiple tumors predicted a good prognosis for patients with DLBCL.

The present study still has certain limitations. First, the SEER database did not include the information of chemotherapy in patients with PTL; thus, the role that chemotherapy alone or in combination with other treatments played in MALT or DLBCL treatment remains unknown. Second, we failed to take into account the presence of comorbidities (other than another cancer), the presence of extranodal disease, the performance status, or the size of PTL as prognostic factors, because information regarding these factors are not available in the SEER database. Third, determining the proper pathologic predictors for survival in People's Republic of China, especially in Eastern China, is difficult due to the small case size.

Conclusion

In conclusion, given the rarity of PTL, conducting prospective randomized trials to assess the prognostic factors is difficult. The current study presents a case series with 28 patients with PTL. Statistical analysis reveals that the age at diagnosis and the median DSS were significantly diverse among different PTL subtypes. The analysis of the SEER database indicated that older age could shorten the DSS of patients with MALT and DLBCL. Lower clinical stage and multiple tumors predicted good prognosis for patients with DLBCL. The multivariate analysis of SEER data identified the following independent prognostic factors for patients with DLBCL: age, treatment modalities employed, clinical stage, and number of other types of cancer. Patients with DLBCL could benefit from surgery alone or in combination with radiotherapy. No available prognostic factor was found in patients with MALT.
