Antibiotic resistance: a rundown of a global crisis

Abstract: The advent of multidrug resistance among pathogenic bacteria is imperiling the worth of antibiotics, which have previously transformed medical sciences. The crisis of antimicrobial resistance has been ascribed to the misuse of these agents and due to unavailability of newer drugs attributable to exigent regulatory requirements and reduced financial inducements. Comprehensive efforts are needed to minimize the pace of resistance by studying emergent microorganisms, resistance mechanisms, and antimicrobial agents. Multidisciplinary approaches are required across health care settings as well as environment and agriculture sectors. Progressive alternate approaches including probiotics, antibiotics, and vaccines have shown promising results in trials that suggest the role of these alternatives as preventive or adjunct therapies in future.

Introduction

Antibiotic resistance is ancient and the “resistome” is a dynamic and mounting problem. Causes of the global resistome are overpopulation, enhanced global migration, increased use of antibiotics in clinics and animal production, selection pressure, poor sanitation, wildlife spread, and poor sewerage disposal system.1,2 Antibiotic treatment is one of the main approaches of modern medicine which is used to combat infections. The “golden era” of antibiotics ranged from the 1930s to 1960s which gave rise to many antibiotics.3 Unfortunately, this era ended because researchers were unable to maintain the pace of antibiotic discovery in the face of emerging resistant pathogens. Persistent failure to develop or discover new antibiotics and nonjudicious use of antibiotics are the predisposing factors associated with the emergence of antibiotic resistance.4

Antimicrobial resistance (AMR) poses a serious global threat of growing concern to human, animal, and environment health. This is due to the emergence, spread, and persistence of multidrug-resistant (MDR) bacteria or “superbugs.”5 MDR bacteria exist across the animal, human, and environment triangle or niche and there are interlinked sharing of these pathogens in this triad. The plausible causes of “the global resistome” or AMR include excessive use of antibiotics in animals (food, pets, aquatic) and humans, antibiotics sold over-the-counter, increased international travel, poor sanitation/hygiene, and release of nonmetabolized antibiotics or their residues into the environment through manure/feces. These factors contribute to genetic selection pressure for the emergence of MDR bacterial infections in the community. Recently, the global consumption of antimicrobials in livestock has indicated the hotspots of antibiotics use across the continents that will have economic and public health impacts.
in the years to come. In food animals, antibiotics are commonly used in cattle, chicken, and pigs and it is projected that in 2030 such use will increase up to 67% in the most populated countries of the world.6

The effective use of an antimicrobial agent is undermined due to the possible tolerance or resistance developed from the very initial time this compound is used. This is true for antimicrobial agents used to treat bacterial, viral, fungal, and parasitic infections. Several physiological and biochemical mechanisms may steer this developing resistance. The intricacy of all the mechanisms associated with the emergence and distribution of the resistance should not be overplayed. Furthermore, lack of elementary data on these specific subjects is a vital concern, which has caused a lack of significant achievements from being made to manage the development of resistance. Worldwide, various institutes and agencies have recognized this serious global public health problem. Many recommendations and resolutions have been proposed, several reports have also been written, but so far little progress has been made. Unfortunately, the increase in antibiotic resistance is a persistent issue.7

The discovery of antibiotics was a defining moment in the history of mankind that revolutionized medicine and saved countless lives. Unfortunately, these “magic bullets” have been accompanied by these emerging resistant strains of pathogens. Currently, medical experts are raising real concern for a return to the preantibiotic age. After the analysis of the available bacterial genomes, it has been concluded that over 20,000 potential resistance genes (r genes) are present, fortunately; however, the functional resistance determinants in various microbes are far less in number.5

During the late 1950s and early 1960s, antibiotic resistance to multiple antimicrobial agents was detected, for the very first time, among enteric bacteria namely Salmonella, Shigella, and Escherichia coli. These resistant strains caused huge clinical, economic losses and loss of life, mainly in the developing world. However, in the developed world it was considered a mild health problem restricted to enteric microbes. This misconception changed in the 1970s when it was observed that Neisseria gonorrhoeae and Haemophilus influenzae are resistant to ampicillin, while in the case of Haemophilus it was further reported to resist tetracycline and chloramphenicol as well. Due to the increasing use of antimicrobials, the incidence of resistance accelerated, particularly in the developing world where these drugs were freely accessible without any prescription. Deprived hygiene settings facilitated the transmission of resistance and insignificant health care funds limited access to novel and effective antibiotics.8

Numerous important organizations, like the Centers for Disease Control and Prevention (CDC), Infectious Diseases Society of America, World Economic Forum, and the World Health Organization (WHO) have declared antibiotic resistance to be a “global public health concern.”9,10 The World Health Assembly requested WHO to propose a global action plan to fight the antibiotic resistance problem.11 Another valuable input to the issue has been the recent publication of a book titled “The evolving threat of antimicrobial resistance – options for action.” In the UK, people voted for a government-sponsored prize of £10 million (Longitude Prize challenge) to create novel solutions in combating antibiotic resistance.12,13 In America, by 2015, President Barack Obama under the recommendations of the US President’s Council of Advisors on Science and Technology ordered the National Security Council to draft a comprehensive national action plan to tackle antibiotic resistance.14,15

Global antibiotic resistance shows no signs of decline, though it may perhaps shift direction. The etiology of antibiotic resistance is multifaceted, and its consequences pose an impact across the globe. Numerous attempts have been made to delineate the diverse aspects of antibiotic resistance and possible solutions required to deal with this global challenge have been tried. However, a principally coordinated campaign is lacking, particularly at the political level worldwide.16 Antibiotics played an unprecedented role in social and medical development, and at present, antibiotics are obligatory in all health care systems. The success of modernized medicine, namely organ transplantation, cancer therapy, management of preterm babies, or a surplus of advanced major surgeries, might not have been possible without effective antibiotic treatment to control for bacterial infections. If effective global action plans are not adopted soon, then we might encounter terrible complications for social, medical, and economic prospects. Here, we try to portray the global magnitude, major etiologies, and consequences and identify key areas that require urgent attention.17

The global economic scenario of antibiotic resistance

An estimation of the exact economic impact of resistant bacterial infections is still a huge global challenge. In this matter, measuring the disease distribution associated with antibiotic resistance is a key prerequisite. Antibiotic resistance is a substantial economic burden to the whole world. In the USA alone, antibiotic-resistant pathogen-associated hospital-acquired infections (HAIs) cause 99,000 deaths annually. In 2006, about 50,000 Americans died due to two common HAIs,
nately pneumonia and sepsis, costing about $8 billion to the US economy.18 Patients with antibiotic-resistant bacterial infections need to stay in the hospital for at least 13 days, adding an additional 8 million hospital days annually. Costs of up to $29,000 per patient treated with an antibiotic-resistant bacterial infection have been reported. In total, economic losses of about $20 billion have been recorded in the US, while losses of about $35 billion annually have also been recorded in terms of lost productivity due to antibiotic resistance in health care systems.15

$35 billion annually have also been recorded in terms of lost

$35 billion annually have also been recorded in terms of lost productivi
due to antibiotic resistance in health care systems.15

According to the analysts of Research and Development Corporation, a US nonprofit global organization, a worst-case scenario may evolve in the coming future where the world might be left without any potent antimicrobial agent to treat bacterial infections. In this situation, the global economic burden would be about $120 trillion ($3 trillion per annum), which is approximately equal to the total existing annual budget of the US health care. In general, the world population would be hugely affected: as of the year 2050, about 444 million people would succumb to infections and birthrates would rapidly decline in this scenario.19,20 These losses are calamitous, but due to data constraints like the inclusion of overall conditions and diseases susceptible to resistance these figures represent incomplete images of the economic costs of antibiotic resistance. Another very significant trait of AMR that was absent in the investigation is the use of antibiotics in livestock and food industry. It is an active participant in the increasing AMR and possibly brings its own expected economic losses. A malpractice of the use of antimicrobials as growth promoters is also found in many developing countries. Since 2006, this practice has been banned in the European Union.21,22

Current estimates of resistance-related costs have limited scope and do not consider the broader social values of antibiotics. These are predisposing factors which steer inaccuracy in the estimation of the actual economic burden that the world is facing due to this issue. To get the precise estimation of the economic ramifications caused, prospective studies should employ macroeconomic methods, which consider all the effects of escalating antibiotic resistance especially the reduction in effectiveness of various antibiotics in modernized medicine. Until we address these issues, the exact estimate of the global economic burden of antibiotic resistance may not be fully calculated.15,23

Antibiotic discovery and supremacy
In various parts of the world, from Greece to China, control of microbial infection has been well documented in the past. In 1928, the discovery of penicillin opened the door to the modern era of medicine. Ever since these “magic bullets” have transformed medicine and saved countless lives. In the 1940s, the very first prescription of antibiotics was made. During World War II, penicillin was considered as the drug of choice and used to control bacterial infections among the armed forces.24,25 Unfortunately, soon after that resistance against penicillin turned out to be a significant clinical concern. So, most of the advancements made in the 1940s were threatened during the 1950s. However, to maintain the use of antibiotic treatment strategies, scientists soon discovered and developed novel β-lactam antibiotics. Howbeit, the first case of methicillin-resistant Staphylococcus aureus (MRSA) was reported in the UK and the US in 1962 and 1968, respectively, the same decade when new antibiotics were applied.24,26

Regrettably, with the passage of time, resistance has been observed to almost all the antibiotics developed during that period. Later in 1972, an antibiotic called “vancomycin” was presented to the clinicians to treat MRSA.24 During that period, it was believed that development of vancomycin resistance was unlikely to occur in clinical settings. However, during the late 1970s and early 1980s few cases of coagulase-negative vancomycin-resistant staphylococci were reported. Until the early 1980s, the pharmaceutical industry developed and introduced many new antibiotics to resolve the resistance issue, and with the passage of time, the pace of antibiotic development staggered, so very few new antibiotics were introduced. Consequently in 2015, after ~70 years since the first patient was treated with antibiotic, bacterial infection became a serious threat to life once again.24,26

Although at present antibiotic resistance emerges as a global threat, there are certain breakthroughs antibiotics have handed to humankind, especially in medicine and surgery. Antibiotics have treated or prevented bacterial infections that may occur during chemotherapy or major surgeries like joint replacement, organ transplant, or cardiac surgery. These magic bullets have also changed the outcome of bacterial infections which extended the average life expectancy. During 1920, expected life spans were 56.4 years in the US; on the other hand, at present, the average life span in the US is about 80 years. Antibiotics have had a parallel useful impact across the globe, such as in the developing world with deprived public health infrastructure, as antibiotics reduce the morbidity and mortality rate caused by bacterial infections in humans and livestock alike.8,25,27

The emergence of antibiotic resistance
Microorganisms underwent Darwinian selection to develop some stringent mechanisms to escape the lethal effects of
antimicrobial substances. Naturally, most of the antibiotics are produced by microbes like saprophytic bacteria or environmental fungi, others are modified synthetic antibiotics, whereas a few are completely synthetic like fluoroquinolones and sulphonamides. Various organisms evolved defensive phenomena against them such as alterations in the target site, inhibition of drug entry or distribution, and enzyme production that may degrade the antimicrobials. For that reason, antibiotic resistance may simply depict the Darwinian competition from natural microbial-derived antimicrobial elements. The functional meta-genomic analysis of soil microbes has revealed an extensive diversity in genetic determinants associated with antibiotic resistance. Although very little has been reported in human pathogens about this aspect, production of enzymes (β-lactamases) is an exceptional example as a naturally present resistance mechanism and has an impact on human health.

It is considered that various antimicrobial molecules produced by saprophytic bacteria impede the growth of other organisms present in that environment, a mutual benefit in such environmental settings, although few findings proposed a more complicated interaction. Primarily, it is suggested that the concentration of antimicrobial substances in the soil appears much lower, and may not be able to inhibit the growth of neighboring bacteria. Second, available data suggest that antimicrobial substances with sublethal concentrations have a significant impact on microbial physiology, microbial evolution, and they may act as effective signaling molecules which may induce host or microbial gene expression. Another important query is that few saprophytic bacteria produce a vital type of broad spectrum antibiotic known as carbapenems. Various genes involved in carbapenems synthesis may also play a part in biofilm formation or quorum sensing. These findings introduce more queries about the unexpected impacts of these antibiotics. This emergence of resistance is not limited to natural antimicrobials only, it occurs against synthetic antimicrobials too.

Causes of antibiotic resistance
At present, the multifaceted etiology of antibiotic resistance has many factors which are at play. These include inadequate regulations and usage imprecisions, awareness deficiency in best practices which steers undue or inept use of antibiotics, use of antibiotics as a poultry and livestock growth promoter rather than to control infection, and online marketing which made the unrestricted availability of low-grade antibiotics very accessible. Primarily, overuse of antibiotics is the principal cause of resistance evolution, as it was also warned by Sir Alexander Fleming that “public will demand [the drug and] then will begin an era … of abuses.” Antibiotics kill sensitive bacteria but allow resistant pathogens to remain which then reproduce and thrive through natural selection. Although overuse of antibiotics is strongly discouraged, there remains overprescription across the globe. Several studies have revealed that treatment indications, agent choice, and antibiotic therapy duration are inappropriate in 30%–50% of the cases. Globally, antibiotics are used as a growth promoter in livestock. According to an estimate, about 80% of the antibiotics are sold in the US only for use as growth supplements and to control infection in animals. In another study, a global map of 228 countries was drawn which depicted the consumption of antibiotics in livestock; it was estimated that the total antibiotic consumption was 63,151 tons in 2010. van Boeckel et al have also projected a 67% rise in antibiotic consumption by 2030 that would approximately double in Brazil, Russia, India, China, and South Africa block of the rapidly developing and highly populated countries of the world.

Drivers of antibiotic resistance transmission
At present, the understanding of various drivers of antibiotic resistance is the key to addressing this global concern. The occurrence of resistance in microbes is a natural process (Figure 1); until now, antibiotic resistance selection is driven using different antibiotics in health care systems, environment, and in agriculture/livestock. Additional important factors which are potent drivers of antibiotic resistance include sanitation settings, infection control standards, water hygiene systems, drug quality, diagnostics and therapeutics, and travel or migration quarantine. In addition to the mutation in various genes residing on the chromosome of the microorganism, exchange of genetic material between organisms plays a vital role in the distribution of antibiotic resistance. Plasmid transmission is the most important phenomenon which may transfer genes of antibiotic resistance to the host cell. Antibiotics may influence this process by inducing the transmission of resistance elements; these antimicrobials may additionally exert a selective pressure to the emergence of resistance. Demonstration of transmission dynamics of resistance has increased the awareness and understanding of how resistant pathogens transmit from human to human. At the community level, feco–oral route is the most important route of transmission especially for resistant pathogens of the
family Enterobacteriaceae, usually due to sanitation failure. Community-acquired (CA)-MRSA is also a good example to understand the transmission dynamics of resistance at the human–human level, which is usually transmitted due to prolonged hospital stay or unhygienic hospital settings. Sexual contact is also a source of transmission for resistant N. gonorrhoeae.39–41

Another very important facet known as “one health” also plays a significant role in the transmission dynamics of antibiotic resistance.28 Irrational use of antimicrobial growth promoters in farm animals is associated with the transmission of resistance to humans via animal products; important pathogens under consideration in this aspect are Salmonella spp. and Campylobacter spp. Additionally, indistinguishable resistant mechanisms have been found in bacteria isolated from humans or animals. Resistant bacteria and mobile genetic elements (MGEs) may make their way from animals to humans through various means.42–44 The influence of the environment toward antibiotic resistance is also a concern.

In the agriculture sector, metals are used as microbicides and may contribute critically to resistance development. The role of sewage systems, pharmaceutical industry pollution, and waste management procedures in human–environment transmission are also well documented. A number of resistant pathogens have been isolated from pre- and posttreatment sewage systems.39,45

**Superbugs and superresistance**

The word “superbugs” denotes microbes with higher morbidity and mortality rate increased due to several mutations providing resistance to various classes of antibiotics. Therapeutic preferences for these resistant microbes are less, and these are associated with a prolonged stay at hospital and increased economic cost. In certain cases, superresistant strains have developed increased virulence and improved transmissibility as well.3 Due to aberrant use of antibiotics, numerous bacterial human pathogens have evolved into MDR types. MDR Mycobacterium tuberculosis is a prominent example from

\textit{S. aureus} is considered as the most notorious superbug. It is a nasal commensal of humans and can cause common skin infections. At present, CA-MRSA with increased acquired virulence has emerged as a major community concern. Although most of the CA-MRSA properties are similar to MRSA, CA-MRSA has some additional characteristics as well such as different \textit{mec} gene clusters and genes encoding the cytotoxic Panton–Valentine leukocidin.\textsuperscript{48,49}

\section*{Antibiotic resistance and virulence}

Bacteria reside on human skin, mucous membrane, and inside the human body as well. Among these, bacteria include harmless organisms, many of them are useful commensals, and few are even essential. However, some are known pathogens which cause infection; these are competent enough to colonize, invade, and harm the host tissue.\textsuperscript{49} Pathogenicity is the ability of a bacterium to cause disease, and a pathogen carries a number of factors that facilitate the bacterium to increase their degree of pathogenicity known as virulence. The most important properties which help a pathogen to cause a disease include toxicity and invasiveness. The ultimate sense of balance of a bacterial disease course may be influenced by virulence and the host immune status. Both host and bacteria have coevolved with time, which may be as long as millions of years. Pathogens have amended virulence to get used to the immune system of the host during this time period.\textsuperscript{51} This is contrary to the evolution of antibiotic resistance which is a relatively recent occurrence mostly in the past five decades after the discovery of antibiotics. It is therefore believed that resistance and virulence have evolved during different eras.\textsuperscript{52}

Regardless of evolutionary differences, these processes share common features, and both processes are indispensable for the survival of bacteria under adverse environments. Antibiotic resistance enables bacteria able to overcome therapeutics and virulence is necessary to fight the host immune system.\textsuperscript{51,55} Second, horizontal gene transfer is the mechanism which both resistance and virulence factors use to transmit the determinants between genera or species. Although other mechanisms like adaptive or compensatory mutations may play their role, the transfer of MGEs might be the key genetic procedure for distribution and coselection of resistance and virulence genes.\textsuperscript{54,55} Thirdly, in the case of intracellular or biofilm producing bacteria, antibiotic resistance is also linked to virulence.\textsuperscript{56,57} Additionally, various properties common to resistance and virulence include cell wall modifications, porins (Figure 2), the direct contribution of efflux pumps, and two-component systems that stimulate or inhibit the gene expression involved in virulence and resistance.\textsuperscript{58-60}

MDR opportunistic pathogens like \textit{Acinetobacter baumanii} and \textit{Pseudomonas aeruginosa} may grow in niches with high antibiotic pressure where several other bacteria may not be able to survive and these pathogens may dislocate the host microbiota as well. This is an example of how antibiotic resistance may improve the virulence or pathogenicity of such pathogens and make these bacteria able to survive in such niches. Therefore, antibiotic resistance might be considered as a virulence factor, particularly in the case of hospital settings where drug-resistant opportunistic bacteria may cause high morbidity and mortality.\textsuperscript{61,62}

\section*{Molecular insights of antibiotic resistance}

In the past two decades, acquired MDR infections have increased due to the production of $\beta$-lactamases (eg, extended spectrum $\beta$-lactamases [ESBLs] enzymes, carbapenemases, and metallo-$\beta$-lactamases), leading to third generation cephalosporin and carbapenem resistance.\textsuperscript{63} Among 21 known AMR genes, the important genes responsible for MDR Salmonella and \textit{E. coli} are AmpC, bla-TEM-1, bla-CTX-M-15, VIM-1, NDM-1, floR, tetG, and the recent mcr-1 gene coding colistin drug resistance.\textsuperscript{64-66} Different mechanisms of resistance are described, and novel transmission vectors and genes are identified or characterized on a regular basis. In general, bacteria may use two mechanisms for resistance: 1) intrinsic resistance and 2) acquired resistance.\textsuperscript{67} The ability of a bacterium to resist the action of a specific antibiotic due to inherent structural or functional properties is known as intrinsic resistance. \textit{Pseudomonas} displays a very good example of intrinsic resistance mechanism, due to the absence of a susceptible target site for a particular antibiotic. Triclosan which is a broad spectrum biocide especially against Gram-positive bacteria and several Gram-negative bacteria as well is incapable of preventing the growth of \textit{Pseudomonas}. Initially, it was supposed that active efflux is the reason behind this resistance, but recently the presence of \textit{fabI} (insensitive allele) encoding an extra enoyl-acyl carrier protein reductase enzyme, which is a target site for triclosan, has been reported.\textsuperscript{68,69} Lipopeptide daptomycin, approved in 2003 for clinical practice, is an active drug
against Gram-positive bacteria; however, it is ineffective against Gram-negative bacteria. The reason behind this is the intrinsic variation in the cytoplasmic membrane composition. Since the cytoplasmic membrane of Gram-negative bacteria has a lesser proportion of anionic phospholipids as compared to Gram-positive bacteria, the efficacy of the Ca\textsuperscript{2+}-mediated daptomycin insertion into the cytoplasmic membrane, which is necessary for the antibacterial activity of daptomycin, is reduced.\textsuperscript{70} Additionally, some antibacterial compounds are unable to cross the outer membrane, also considered as a way of intrinsic resistance. In Gram-positive bacteria, vancomycin inhibits peptidoglycan crosslinking by targeting d-Ala-d-Ala peptides while in the case of Gram-negative bacteria, vancomycin cannot pass through the outer membrane. By using high-throughput tools of high-density genome mutant libraries in \textit{P. aeruginosa}, \textit{S. aureus}, and \textit{E. coli}, various genes associated with intrinsic resistance to different classes of antibiotics like β-lactams, aminoglycosides, and fluoroquinolones have been identified in recent times.\textsuperscript{71,72} As an example, inactivation of redundant \textit{E. coli} genes identified putative targets for susceptibility phenotyping, like FabI, SapC, RecQ, TrxA (thioredoxin), TrxB (thioredoxin reductase), DacA, and the d-Ala-d-Ala carboxypeptidase. Inhibition of these genes may significantly stimulate drug activity like triclosan, rifampicin, aminoglycosides, nitrofurantoin, and some β-lactams.\textsuperscript{72} In addition to the intrinsic mechanism of resistance, bacteria may acquire antibiotic resistance as well. Various other mechanisms may also help bacteria to acquire resistance including antibiotic efflux or poor drug penetration resulting in the reduction of the intracellular concentration of antibiotic, modification of the antibiotic target site due to posttranslational target modification or genetic mutation of the target, and inactivation of the antibiotic by modification or hydrolysis.\textsuperscript{73–76} Plasmid coding colistin-resistant (\textit{mcr-1} dependent) \textit{E. coli} was first isolated from raw meat, animals, and humans in China.\textsuperscript{77} In Pakistan, \textit{mcr-1} harboring \textit{E. coli} was also reported from migratory birds and from human clinical isolates. MDR (ESBLs, quinolones) \textit{E. coli} was also reported from poultry farms, wild birds, pigeons, dogs, and humans.\textsuperscript{78}

**Therapeutic strategies to combat antibiotic resistance**

Control of infection has long been a serious concern of the evolutionary race, regardless of the clinical proof that approaches based on small molecule monotherapy are inadequate in resistance settings. Assessment of various nominees for infection control under developmental process suggests that the focus of research would be on discovery and identification of novel antibiotics. Unfortunately, bio-therapeutics...
like antibiotics, novel combination remedies, and drug delivery procedures still lag behind the production of novel small molecules that are usually an extension of the present drug classes. Approaches of systemic monotherapy where resistance has overtaken drug development are inadequate worldwide. Therefore, instead of combating bacterial evolution, control strategies might serve better by pursuing resistance mechanisms based on genetic inspiration, for example, furanones deployed by red sea algae to disturb the quorum sensing of resistant bacteria.

Though the role of biologics in the control of bacterial infection is in its infancy, its potential to combat MDR cannot be overlooked. Small molecules would always have a key role in the control of infection; however, on the basis of biological inspiration the search for an effective drug candidate may possibly be pursued more logistically. Various tools used for drug development are essential to handle the shortcomings of biologics, like controlled delivery options, partial in vitro stability, inadequate high-throughput, advanced screening tools, inefficient pharmacokinetics, and comparatively unknown pharmacodynamics, and are not as radical as those accessible for the development of small molecules. By chance, a vast potential subsists between biologics combinations, molecules based on biological inspiration, and drug delivery tools. Therefore, a paradigm shift like cancer and complex viruses might be adapted to eradicate susceptible bacteria, handle antibiotic resistance, and shield the host microbiota. This type of approach may be crafted through the combination of conventional antibiotics, novel adjuvants, and viable limited delivery strategies. In contrast to various expensive development models which often fail in trials, advanced bioinformatics to determine effective combination delivery and new targets will possibly bring substantial benefits.

Implementation of various methods of antibiotic resistance is very significant, as it has a substantial impact on humans and livestock. Although the resolutions have been anticipated, with few being thrown to tackle the crisis, to date very little action has been taken toward these solutions. At present, antibiotics are obligatory in health settings, and the economic, social, and medical costs would be calamitous due to disorganized effort. In the face of rising antibiotic resistance, the antibiotic efficacy looks increasingly bleak. Epidemiological trends in MDR bacteria must be considered in developing treatment strategies for infection control. Optimistically, constant highlighting of the problem would encourage researchers to adopt novel strategies to control bacterial infection with the following criteria: discovery of novel antibiotics, anticipation and prevention of antibiotic resistance, and protection of host microbiota. Preeminent approaches that come across with this criterion would help the formation of novel combination strategies together with smart and local delivery tools, for example, directed nanoparticles, liposomes, and infection-responsive polymer-controlled delivery. Alternative approaches to antibiotics that are presently in clinical trials are listed in Table 1.

The use of nanotechnology is emerging in medicine and it is not astounding to see these technologies being applied for the management of the antibiotic resistance menace. Nanoparticles can be utilized for the therapeutic management of infections in different ways. They can be coupled with existing antimicrobial agents for enhancement of their physiochemical behavior against drug-resistant microbes. Second, the colloidal forms of zinc, silver, copper, and titanium can itself be used as antimicrobial agents. Although the principal targets of antibiotics include the inhibition or disruption of bacterial cell wall, inhibition of proteins, and nucleic acids synthesis, nanoparticles are reported to affect the respiration system and thereby generation of reactive oxygen species that ultimately leads to bacterial death. Nanoparticles also target the bacterial cell wall; therefore, for example, silver nanoparticles can be coupled with the relevant antibiotics to enhance their antibacterial action through synergy.

Antimicrobial peptides (AMPs) are emerging antimicrobial agents found in animals, microorganisms, and plants and have a broader spectrum especially active against different bacteria, fungi, and protozoans. The amphipathic nature of AMPs enables interaction and insertion into the cell wall and cellular membranes of microbes. Although AMPs usually demonstrate antimicrobial activity because of damage to the cellular membranes, they can target other proteins, DNA, RNA, and regulatory enzymes and therefore seem to be a promising substitute for classical antibiotics. However, the development of resistance to AMPs is expected as soon as AMPs are used in clinical antibiotics. Although AMPs usually demonstrate antimicrobial activity because of damage to the cellular membranes, they can target other proteins, DNA, RNA, and regulatory enzymes and therefore seem to be a promising substitute for classical antibiotics. However, the development of resistance to AMPs is expected as soon as AMPs are used in clinical antibiotics. Although AMPs usually demonstrate antimicrobial activity because of damage to the cellular membranes, they can target other proteins, DNA, RNA, and regulatory enzymes and therefore seem to be a promising substitute for classical antibiotics.

**Global action plan to control the menace of antibiotic resistance**

The global burden of AMR has no signs of receding, rather it piles up the pressure on human and veterinary medicine. Akin to global warming, AMR is an ecological calamity of
indeterminate magnitude and has no apparent way out. Until the first decade of the current century, scientists and clinicians were not up-to-the-minute about AMR, whereas resistant bacteria had been identified before the discovery of penicillin.98 Consequently, WHO made a landmark by declaring and promoting AMR as a global health concern. The agenda for such global health concerns is at the developmental stages; for example, a book named “The evolving threat of antimicrobial resistance – options for action” is a valuable addition to the archive.99 Few countries across the globe reported the control of various resistant pathogens especially MRSA, but reasons behind the decline in the resistance of these microorganisms are disputed. For example, the apparent success to confine MRSA attained in the US by practicing various schemes of hygiene and screenings has been thrown aside because some supplementary factors like overall national decline in the prevalence of MRSA may be a strong reason of MRSA control.100 In Europe, the same actions have also been significantly found at the national level. Scientific fraternity must appreciate such arguments because we are still struggling to recognize the main interventions prerequisite for AMR control. Perhaps, the eradication of AMR is unattainable but its progression may be decelerated.101,102 Different global agencies such as the Global Antimicrobial Resistance Surveillance System under WHO should work for the control of antibiotic resistance; Food and Agriculture Organization, CDC, and Office International des Epizooties are making strong efforts to control antibiotic resistance. Other programs dealing with the global threat of antibiotic resistance include the Global Health Security Agenda (GHSA), Antimicrobial Resistance Action Package (GHSA Action Package Prevent-1).103,104

The fallacy about the enormity and peril of AMR mapped the current epidemic. Additionally, studies showing the burden of AMR influenced the think tanks to pursue the issue with urgency. Countries that crafted inclusive national plans remain successful in controlling AMR. These approaches include cautious use of antibiotics, surveillance of antimicrobials by employing the “One Health Approach,” advancement of health care setup, development of health insurance policies, restricted drug promotion, consistent disease control strategies, and stewardship plans in the community.17 On the other hand, these strategies demand patience and time to be organized. Furthermore, these require a comprehensive endorsement from the government authorities with ample funds. In developing countries, progress is at a very low pace,
although some Asian countries including India, in particular, have taken some courageous steps toward AMR control in recent times, for example, the Chennai declaration.105

Diagnostics pose a significant impact in the setting up of AMR because it drives clinicians to use antibiotics imprudently. Diagnostics is a pressing issue especially in developing countries because they still rely on conventional microbiological tools to identify bacteria. These gaps could be bridged by developing personalized medicine established based on new and efficient molecular diagnostic tools that would be very helpful to identify patients who actually need antibiotic therapy. One Health Approach could be a very useful tool to study the human–animal interface and guide researchers to design novel screening tools. This subject is of unique importance and must be taken up earnestly because the transmission pathway of AMR between all components (human, animal, and environment) of one health has been established.17,106

Unwise and irrational use of antibiotics is also a salient factor associated with AMR especially in low and middle income countries (LMICs). Antibiotics are used imprudently due to many reasons, such as patient’s contentment over a prescription of the physician, inappropriate information about antibiotics, improper diagnosis, quackery especially in developing countries, and sinfully, temptations of the pharmaceutical industry for the physicians. Having a dearth of new antibiotics, it is quite difficult to confront this portion of the problem.107 Innovation in antibiotic development, combination therapy, and technological development are indispensable.108 Another aspect of colossal importance in this regard is the integration of the health care system and antibiotic stewardships. Data about the impact of AMR on health and economy of developing countries are inadequate. LMICs have a dire situation in terms of clinical outcomes of many fatal bacterial diseases like newborn sepsis, typhoid, etc. So, the task is not simply to use conventional options but some customized control policies should also be applied; for example, resistant pathogens should be prioritized like MDR M. tuberculosis. Up to the tertiary level, WHO recommendations on infection and disease control should be followed. Comprehensive data should be collected by taking all the national stakeholders including government, academia, and industry on board. Additionally, the industry–academia interface should be improved as both academia and industry have made some fundamental mistakes in the past. First, in the late 20th century, academia and researchers had a mistaken belief about the elimination of infectious diseases and industry-produced antibiotics enormously. Second, although financial incentives in the form of research grants were provided to the academia and pharmaceutical industry, an inadequate proportion was allocated to academia and industries for the generation of sufficient novel classes of antimicrobial agents as compared to the surge of antibiotic resistance.109 In atonement, a group of experts named as Infectious Disease Society of America submitted a 10×20 plan; this was about the development of 10 novel safe and effective antibiotics by the end of 2020.110

Use of alternative therapies for the treatment and control of infectious diseases could also be a different and a prolific option to fend off AMR. These therapies include anti-virulence strategies (to play with the virulence factors of bacteria), biological therapies (use of monoclonal antibodies, insulin, erythropoietin, etc), and vaccines (vaccines against MRSA, MDR M. tuberculosis).111,112 Moreover, herbal medicines have elusive properties; there is a strong viewpoint that it could be a practicable alternate option.

Conclusion
We should seek to increase our knowledge regarding the extent of the AMR issue. Comprehensive, unfailing data collection is crucial in AMR control. Current angst about this issue is due to inadequate information. One cannot predict the future scenario with surety at this stage but with the scarcity of novel antibiotics, the control of AMR seems very difficult. Multipronged strategies should be adopted to confront this issue. Constant and refreshing education of medical students, physicians, and pharmacists is required. Regulations should be implemented with strict monitoring of antibiotic use as part of the policy. A global and interdisciplinary approach must be considered for the development of new screening and diagnostic tools. Ecological and environmental aspects of the issue need not be ignored; all the elements of “one health” should be part and parcel of the control policy. Alternative strategies may also play a fruitful role, especially in developing countries. Current global interest indicates that AMR is not an unheeded issue anymore. Albeit this attention is not itself adequate to combat AMR, a global code of conducts implementing all the options of action against AMR might eliminate AMR in the future. Alternatives to antibiotics such as probiotics and lytic bacteriophages can help to decrease the burden of AMR globally. The spread and sharing of AMR can be contained by the rational use of antibiotics, infection control, immunization, promoting good practices in food supply, and control of person-to-person spread by screening, treatment, awareness, and education. At the national, regional, and global levels, the tracking, bio-surveillance, and response and prevention strategies of AMR and MDR pathogens may help to control the “global resistome.”
