Background: Transversus abdominis plane (TAP) block can provide effective analgesia for abdominal surgery. However, many randomized controlled trials (RCTs) have shown controversial results in hysterectomy. We conducted a meta-analysis of RCTs to investigate the effectiveness of TAP block after hysterectomy.

Methods: Studies were gathered from PubMed, MEDLINE, EMBASE, Cochrane Library, Web of Science, and ClinicalTrials.gov databases up to March 2018. RCTs involving TAP blocks in women undergoing hysterectomy were selected. The primary outcome of mean 24 hours morphine consumption and other outcomes, such as time to first request for analgesic, rest, and pain scores on movement at different times, and rates of nausea and vomiting, were compared between TAP block and no or sham block groups.

Results: A total of 841 participants were included in the 13 selected RCTs. Compared with no or sham blocks, TAP block reduced mean 24-hour morphine consumption in abdominal hysterectomy (AH) (weighted mean difference [WMD] –10.77 mg, P=0.04) but not in laparoscopic hysterectomy (LH)/robotic-assisted hysterectomy (RH) (WMD –1.39 mg, P=0.24). TAP block in AH prolonged analgesic time and reduced nausea and vomiting rates. TAP block also reduced the postoperative pain score at rest and on movement at different times in the AH subgroup, but it did not significantly reduce the postoperative pain score at rest, 6–8, and 24 hours, as well as the pain score on movement at 2, 6–8, and 24 hours in the LH/RH subgroup.

Conclusion: TAP block is an effective analgesic for AH. TAP block can reduce postoperative morphine consumption in AH and pain scores at rest and on movement for AH without increasing side effects. However, TAP block has limited analgesic effects for women undergoing LH/RH, as it does not reduce postoperative morphine consumption and pain scores at rest and on movement.

Keywords: TAP block, ultrasound-guided, hysterectomy, meta-analysis, abdominal, laparoscopic

Introduction

Hysterectomy is one of the common surgical procedures leading to severe postoperative pain in women.1 Poor pain control after hysterectomy is associated with increased length of stay and recovery, and it also has an impact on psychological changes, quality of life, and patient satisfaction.2 Adequate control of pain can prevent the development of chronic pain after hysterectomy.3 Opioids are routinely used to relieve postsurgical pain.4 However, the use of opioids will increase side effects, such as nausea and vomiting, as well as increase the risk of long-term abuse.5

Since the first description of the transversus abdominis plane (TAP) block in 2007,6 many studies have reported that TAP block is a useful strategy to reduce opioid consumption and support the management of postoperative pain for patients.
undergoing abdominal surgery, including hysterectomy.\textsuperscript{7–9} However, other studies have demonstrated that ultrasound-guided TAP block has no effects on pain control and postoperative opioid consumption after hysterectomy.\textsuperscript{10,11} Therefore, the effectiveness of TAP block for hysterectomy still remains controversial.

Although previous meta-analyses have shown that TAP block is safe and effective,\textsuperscript{12,13} these meta-analyses included abdominal surgery in general and were not specific for hysterectomy. There was a meta-analysis of TAP block for hysterectomy in 2013, but many new clinical trials have been conducted in recent years.\textsuperscript{14} Although another meta-analysis\textsuperscript{15} evaluated the analgesic and opioid-sparing effects of TAP block for elective hysterectomy, this study did not pool the result via subgroup analysis based on the type of surgery. To our knowledge, the abdominal incisions of abdominal and laparoscopic or robotic-assisted surgery are completely different, and TAP block was designed to anesthetize the nerves supplying the anterior abdominal wall.\textsuperscript{16} Therefore, it is necessary to further confirm the effect of TAP block in hysterectomy. Here, we conducted a meta-analysis of randomized controlled trials (RCTs) to determine the effectiveness and safety of TAP block after hysterectomy.

**Methods**

**Search strategy**

We applied the recommendations of the PRISMA statement.\textsuperscript{17} Literature searches were performed in the PubMed, MEDLINE, EMBASE, Cochrane Library, Web of Science, and ClinicalTrials.gov databases up to March 2018. The Medical Subject Headings (MeSH), common keywords, and their comprehensive combination included “transversus abdominis plane block” OR “TAP block” OR “transversus abdominis” OR “transverse abdominis” OR “transverse abdominis plane block” AND “hysterectomy” OR “hysterectomies”. Search results were limited to English.

**Inclusion and exclusion criteria**

Two authors (HZ and JP) performed the searches and independently reviewed and extracted data from each study. The search results were compared, and disagreements in opinions were resolved by further discussion. The inclusion criteria were as follows: 1) including women who underwent hysterectomy regardless of abdominal, laparoscopic, or robotic-assisted surgery; 2) including women who received TAP block pre- or postoperation; 3) being an RCT; and 4) being a comparative study between TAP block and sham or no block groups. Exclusion criteria were as follows: 1) being a nonrandomized study; 2) failing to focus on TAP block compared with sham block or no block; 3) being a case report, review paper, or unpublished literature; and 4) undergoing a surgery other than hysterectomy.

**Risk of bias in studies**

The Cochrane Collaboration tool was used to assess the risk of bias in the included studies, which included random sequence generation, allocation concealment, blinding of participants and personnel, blinding of outcome assessment, incomplete outcome data, selective reporting, and other biases.

**Data extraction**

All data were extracted onto a standard form by HZ and JP: 1) characteristics of the studies, including year, name of author, group, and number of patients; 2) characteristics of study participants, including age and body mass index (BMI); 3) characteristics of hysterectomy, including surgical approach, anesthesia method, block timing, drugs used in the block, and pain assessment; 4) characteristics of outcome measures, including primary outcomes, such as mean 24-hour morphine consumption, and secondary outcomes, such as time to first request for analgesic, pain score at rest, and pain score on movement at different times postoperatively, including 2, 4, 6–8, 12, 24, and 48 hours between TAP group and control group, or TAP block combined with adjuvants group and TAP group, or preoperative group and postoperative group; and (5) adverse events, including nausea and vomiting. For the purpose of calculation, the VAS of 0–100 for pain intensity was converted to scales from 0 (no pain) to 10 (worst possible pain).\textsuperscript{18} As some studies evaluated pain score either at 6 or 8 hours postoperation, we merged the pain score at 6 and 8 hours to “6 to 8 hours” for this period. Data of mean values, SDs, standard errors (SEs), 95% CIs, number of events, and total number of participants were extracted from each study. If the literature only provided the median, range, and sample size, we calculated the mean values and SDs in accordance with previous study.\textsuperscript{19} In addition, data in charts were extracted by means of Engauge Digitizer 4.1. If the study included two groups of TAP block, the combined mean values and SDs were calculated according to the formula of the Cochrane Handbook for Systematic Reviews of Interventions, version 5.1.0.

**Subgroup meta-analysis**

Hysterectomy was carried out by abdominal hysterectomy (AH), laparoscopic hysterectomy (LH), or robotic-assisted hysterectomy (RH). The type of surgery performed will
cause different results, and the LH and RH similarly use multiple small incisions. Therefore, we performed a sub-
group meta-analysis to assess the effectiveness and adverse
events between the TAP block group and the control group
with regard to the type of surgery, as in a previous meta-
analysis\(^{20}\) that included AH and LH/RH subgroups.

**Statistical analysis**

We conducted a meta-analysis when two or more trials
reported similar outcomes. Results of meta-analysis were
analyzed by Review Manager software, version 5.3 (Cochrane
Collaboration, Oxford, UK). For dichotomous variables
and continuous variables, the ORs and weighted mean differences
(WMDs) were calculated, respectively, and reported with 95% CIs. \( F \) was used to evaluate heterogeneity with predetermined
thresholds for low (25%–49%), moderate (50%–74%), and
high (>75%) levels. The chi-squared test with significance set
at \( P<0.10 \) was used to measure heterogeneity of the results
among the included studies. The \( F \) statistics quantified the
heterogeneity. Results were aggregated and analyzed using a
fixed-effects model with \( F<50\% \). If the \( F \) statistic was higher
than 50\%, a random-effects analysis was performed. \( P<0.05 \)
of a two-tailed test was considered to be statistically significant
in all tests. Publication bias of included trials in our meta-
analysis was evaluated via funnel plots.

**Results**

**Literature search and quality assessment**

A total of 641 studies were identified after the initial search
from PubMed (n=364), MEDLINE (n=53), EMBASE
(n=95), Cochrane Library (n=73), Web of Science (n=49),
and ClinicalTrials.gov (n=7) databases. After removing
185 duplicates, the titles and abstracts of 456 studies were
screened. In total, 413 studies were excluded after records
screening. The full texts of the remaining 43 articles were
retrieved for full evaluation. At last, 13 prospective ran-
domized controlled studies published from 2008 to 2016
were included for quantitative synthesis (Table 1).\(^{7,10,11,21–30}\)
The flow diagram of study selection is summarized in
Figure 1. Potential sources of methodological bias according
to the Cochrane Collaboration Risk of Bias tool were
evaluated in all the included studies and summarized in
Figures 2 and 3. Overall, the majority of trials had a low
risk of bias.

**Characteristics of study participants**

A total of 841 participants were included in the 13 RCTs
selected. Among the 13 studies, women in eight stud-
ies\(^{7,21,22,24,25,27,28,30}\) underwent total or partial AH and women
in five studies\(^{10,11,23,26,29}\) underwent LH/RH. All trials used
standard general anesthesia. Nine studies\(^{7,10,11,21,23,25,27–30}\) performed TAP block preoperatively, and three studies\(^{22,24,26}\)
performed TAP block postoperatively. One study\(^{21}\) compared the effects of preoperative and postoperative approaches to
TAP block. Primary outcomes of the included studies were
morphine consumption, postoperative pain, and quality of
recovery score (QoR-40), and most included studies revealed
no significant differences between groups regarding age and
BMI or weight (Table 1).

**Effect of TAP block on analgesic after hysterectomy**

Seven studies\(^{7,10,11,23,27–29}\) assessed the mean 24-hour mor-
phine consumption for the effect of TAP block for hysterectomy. Compared with no or sham block, TAP block did
not reduce mean 24-hour morphine consumption in any
hysterectomy (WMD –4.80 mg, 95% CI –9.82 to 0.22
mg, \( P=0.07 \)) with high heterogeneity (\( I^2=76\% \)). However,
in subgroup analysis, TAP block in AH reduced mean
24-hour morphine consumption (WMD –10.77 mg, 95%
CI –20.81 to –0.73 mg, \( P=0.04 \)) with high heterogeneity
(\( I^2=71\% \)). In addition, TAP block in LH/RH had no sig-
nificant difference in mean 24-hour morphine consumption
(WMD –1.39 mg, 95% CI –3.72 to 0.94 mg, \( P=0.24 \)) with
no heterogeneity (\( I^2=0\% \)) (Figure 4A). For women’s first
request for analgesic after operation, the pooled result of
four studies\(^{7,21,25,30}\) on TAP block in AH had a longer time
than no block or sham block (WMD 61.87 minute, 95%
CI 24.78 to 98.95 minute, \( P=0.001 \)) with high heterogeneity
(\( I^2=91\% \)) (Figure 4B).

**Degree of pain of TAP block vs no or sham block**

Pain score at rest for TAP block compared with no or sham
block was assessed with the AH and LH/RH subgroups at 2
hours in nine trials,\(^{7,10,11,21,22,24,26,29}\) at 6–8 hours in eight tri-
als,\(^{7,11,21,22,24,27–29}\) at 12 hours in three trials,\(^{7,21,24}\) at 24 hours
in 10 trials,\(^{7,10,11,21–23,26–29}\) and at 48 hours in three trials.\(^{7,21,24}\)
TAP block significantly reduced the pain score at rest at 2 hours
(WMD –1. 41, 95% CI –2.57 to –0.26, \( P=0.002 \)), at 6–8
hours (WMD –1.29, 95% CI –1.91 to –0.68, \( P<0.0001 \)), at
12 hours (WMD –1.25, 95% CI –2.23 to –0.27, \( P=0.01 \)), and
at 48 hours (WMD –1.27, 95% CI –1.91 to –0.62, \( P=0.0001 \))
postoperatively in the AH group compared with the control
group with high heterogeneity (\( I^2>50\% \)) (Table 2). In the LH/
RH subgroup, although TAP block significantly reduced the

pain score at rest at 2 hours (WMD –0.83, 95% CI –1.52 to –0.14, \(P=0.02\)), it did not significantly reduce the pain score at
rest at 6–8 hours (WMD –0.61, 95% CI –1.51 to –0.29, \(P=0.19\)) and
24 hours (WMD –0.64, 95% CI –1.45 to 0.16, \(P=0.12\)) with high heterogeneity (\(I^2>50\%\)) (Table 2) (Figure S1).

For pain score on movement, the pooled results of five trails\(^7,21,22,28,30\) for AH showed that TAP block significantly reduced when compared with the control group at 2 hours (WMD –1.91, 95% CI –3.30 to –0.53, \(P=0.007\)) with high heterogeneity (\(I^2=98\%\)). The pooled results of trials showed that
Figure 3  Cochrane collaboration’s risk of bias summary: evaluation of risk of bias items for each included study.

Notes: Green = low risk of bias. Red = high risk of bias. Yellow = unclear risk of bias.
TAP block significantly lowered the pain score on movement compared with the control group at 6–8 hours (WMD −1.39, 95% CI −2.16 to −0.63, P=0.0004), at 12 hours (WMD −1.60, 95% CI −2.00 to −1.20, P<0.0001), at 24 hours (WMD −1.45, 95% CI −2.14 to −0.76, P<0.0001), and at 48 hours (WMD −1.62, 95% CI −1.32 to −0.93, P=0.0001). For the LH/RH subgroup, the pooled results of two trials at 2 and 24 hours showed no significant difference in the pain score on movement between TAP block and no or sham block at 2 hours (WMD 0.22, 95% CI −0.62 to 1.06, P=0.61; WMD 0.11, 95% CI −0.68 to 0.90, P=0.78). Moreover, TAP block showed a significantly higher pain score on movement than no or sham block at 6–8 hours (WMD 0.98, 95% CI 0.58 to 1.38, P<0.0001) with no heterogeneity (I²=0%) (Table 2) (Figure S1).

Side effects of TAP block for hysterectomy

Moreover, we investigated the side effects, such as the rate of nausea and vomiting, of TAP block. Six studies7,21,24,25,27,29 compared TAP block with no or sham block, and the rate of nausea and vomiting after operation was significantly lower than no or sham block with low hetero-
geneity (OR 0.49, 95% CI 0.30 to 0.79, P=0.003, I²=48%) (Figure 4C).

Sensitivity analysis
In order to confirm the effect of TAP block in the LH/RH subgroup, we conducted a sensitivity analysis on this subgroup. As we only included one study of RH, we evaluated the effect of TAP block in LH studies only. The results of sensitivity analysis on this subgroup. As we only included one study of RH, we evaluated the effect of TAP block in LH studies only. The results of mean 24-hour morphine consumption, pain score at rest at 2 hours and pain score at rest at 24 hours showed similar results for all the studies (Table 3).

Discussion

We conducted a meta-analysis of RCTs to evaluate the analgesic effect of TAP block after hysterectomy. To our knowledge, this meta-analysis updated the current understanding of the effects of TAP block for hysterectomy. Compared with the previous meta-analysis of TAP block after hysterectomy, our meta-analysis included more studies and patients with different types of hysterectomy and further investigated morphine consumption at 24 hours and pain scores at rest and on movement at different times based on two subgroups, AH and LH/RH. In addition, we also reported the pooled results of the rate of nausea and vomiting with TAP block. Compared with the recent meta-analysis pointing out that the TAP can have moderate opioid-sparing effects after hysterectomy, we further confirmed that the TAP block can provide effective analgesia for AH. However, from our results, the effect of TAP block in LH/RH is limited.

Although the analgesic effect of TAP block has been confirmed in previous meta-analyses in several surgeries, the effects of TAP block in hysterectomy are still controversial. For women who underwent hysterectomy, although many studies had shown effective analgesia, we found some studies focusing on LH/RH that showed TAP block could not provide effective analgesia. Therefore, the evaluation of the effectiveness of TAP block for hysterectomy based on different surgical approaches is necessary. We used the result of mean 24-hour morphine consumption as the primary outcome to assess the analgesic effect of TAP block in different subgroups. The pooled results of different subgroups show that TAP may reduce mean 24-hour morphine consumption after hysterectomy with marginal significance. However, for further subgroup analysis, our results show that TAP block significantly reduced mean 24-hour morphine consumption and prolonged the time to first request for analgesic in AH only, and TAP block has limited effectiveness for participants who underwent LH or RH. Similarly, TAP block also significantly reduced the pain scores at rest and on movement postoperatively at different times in AH but not in LH or RH. In our pooled results, we demonstrated that TAP block did not reduce analgesic consumption in LH or RH.

The possible reason is that pain after hysterectomy mainly originates from somatic and visceral components, and TAP block is a peripheral nerve block technique that mainly reduces the pain from skin and muscle of the abdominal wall via blocking thoracolumbar nerves (T6-L1). Pain from the skin incisions in AH is considerably worse than that in LH or RH. Several studies have also demonstrated low VAS scores after LH or RH compared with open hysterectomy, indicating that LH or RH may be less painful because of smaller incisions and, to an extent, that the basic treatment with NSAIDs may be sufficient for LH or RH.

the TAP block is not believed to cover visceral pain, unless there is a systemic effect by absorption of the local anesthetics into the systemic circulation.39 This might be the reason why TAP block shows more of an analgesic effect in ABs compared with minimally invasive procedures. Therefore, our meta-analysis confirmed the result of the limited analgesic effect of TAP block in LH patients.

Some studies39,40 have been concerned whether TAP block will increase the rate of nausea and vomiting after hysterectomy. Interestingly, our pooled results showed that TAP block significantly reduced the rate of nausea and vomiting after the operation. This result is similar to the previous meta-analysis33 of TAP block performed in different abdominal surgeries. Nausea and vomiting and delayed recovery of bowel mobility after the operation are the main complications of opioid consumption. As TAP block significantly reduced pain levels and led to a reduction in postoperative opioid consumption, it can potentially reduce the side effects, such as nausea and vomiting. This result was also consistent with a previous study that found that TAP block did not affect the recovery of gastrointestinal function.41 For other outcomes, such as rehabilitation after operation and patient satisfaction, our included studies did not have sufficient data to pool the results. However, a current study42 reported that TAP block did not significantly reduce the time to ambulation after AH, and another retrospective study43 recently reported that TAP block did not reduce the total length of hospital stay. Moreover, postoperative QoR-40 was assessed for the effect of TAP block in LH, and the scores of comfort, emotions, and independence had no significant difference.11 Therefore, these current studies showed that TAP block is a safe method for hysterectomy but does not provide significant improvement in recovery of patients after hysterectomy. More RCT studies are still needed to evaluate the effect of TAP block in perioperative recovery outcomes after hysterectomy.

Despite some interesting findings, the results of our updated meta-analysis still have some limitations. First, although we set strict inclusion criteria and carried out subgroup analysis, the heterogeneities of some results remained high. Factors such as different doses and types of anesthetics and different postoperative analgesic methods may impact the heterogeneity of the meta-analysis. Second, more RCTs with larger sample sizes in these fields are still needed to strengthen the results of meta-analysis. Finally, because of limited outcomes of included studies, the effect of TAP block on the postoperative recovery of patients undergoing hysterectomy still needs to be further determined.

**Conclusion**

Our meta-analysis showed that TAP block is an effective analgesic for women who underwent AH. In addition, TAP block can reduce postoperative morphine consumption and pain scores at rest and on movement for AH. Also, TAP block will not increase the side effects of nausea and vomiting. However, TAP block has limited analgesic effects for women who underwent LH/RH, as it did not reduce postoperative morphine consumption and pain scores at rest and on movement. Overall, more RCTs with larger patient cohorts with perioperative recovery outcomes are still essential to further demonstrate the value of the robotic approach.
