Effect of angiotensin receptor blockade on endothelial function: focus on olmesartan medoxomil

Carlos Ferrario
Hypertension and Vascular Disease Center, Wake Forest University School of Medicine, Winston-Salem, NC, USA

Abstract: Endothelial dysfunction is the common link between cardiovascular disease risk factors and the earliest event in the cascade of incidents that results in target organ damage. Angiotensin II, the terminal pressor effector arm of the renin-angiotensin-aldosterone system, increases blood pressure (BP) by vasoconstriction and sodium and fluid retention, and has a pro-oxidative action that induces endothelial dysfunction and contributes to vascular remodeling. Angiotensin receptor blockers (ARBs) reduce BP and morbidity and mortality in patients with hypertension, ventricular hypertrophy, diabetes mellitus, and renal disease. Olmesartan medoxomil is a long-acting, well-tolerated, effective ARB that prevents or reverses endothelial dysfunction in animal models of atherosclerosis, hypertension, diabetes, nephropathy, and retinopathy. Olmesartan medoxomil, a prodrug of olmesartan approved for the treatment of hypertension, has been shown to ameliorate endothelial dysfunction in patients with hypertension or diabetes. In randomized studies, the drug reduces vascular inflammation and the volume of large atherosclerotic plaques, increases the number of regenerative endothelial progenitor cells in the peripheral circulation, improves endothelial-dependent relaxation, and restores the normal resistance vessel morphology. Importantly, the impact of olmesartan medoxomil on endothelial dysfunction is thought to be independent of BP lowering.

Keywords: endothelial dysfunction, angiotensin receptor blocker, olmesartan medoxomil, hypertension, atherosclerosis

Introduction
Major advances in the treatment of cardiovascular disease (CVD) have been accompanied by the development of effective prevention strategies. In spite of these advances, CVD continues to be the leading cause of death in most countries in the world. The ongoing epidemic of obesity and increasing prevalence of diabetes mellitus and chronic kidney disease will further contribute to keeping diseases of the heart and blood vessels as the predominant cause of cardiovascular mortality.

The common link between CVD risk factors such as hypertension, diabetes, and smoking is now recognized to be vascular endothelial dysfunction. Under normal circumstances, the vascular endothelium influences vessel tone and modulates structure, vessel permeability, adhesion and migration of inflammatory cells, and hemostasis. In addition, the healthy vascular endothelium has a role in the prevention of oxidative damage. In contrast, endothelial dysfunction may be one of the earliest events initiating the cascade of maladaptive changes that contribute to target organ damage.

Endothelial dysfunction of the coronary arteries is associated with an increased CVD risk. In addition to the conventional cardiovascular risk factors (coronary artery disease [CAD], age, and body mass index), markers of endothelial dysfunction were identified as independent predictors of adverse events during a mean of 46 months...
of follow-up in a prospective study in patients undergoing
cardiac catheterization.9 Markers of endothelial dysfunc-
tion that predicted adverse outcomes included the change
in coronary vascular resistance (ACVR) after intracoronary
administration of acetylcholine and epicardial constriction
with acetylcholine. Survival was improved in patients with
the best microvascular responses after a 2-minute intracoro-
nary infusion of acetylcholine.9

Carotid artery intima-media thickness (IMT) is linearly
related with the risk of myocardial infarction (MI) and
stroke.10 A recent meta-analysis of eight studies showed that
the risk of MI increased by approximately 25% and the risk
of stroke increased by approximately 15% for each increase
of one standard deviation in carotid artery IMT.10 Other
studies have demonstrated reduced endothelial vasodilator
capacity in siblings of hypertensive subjects.11,12 The common
factor responsible for this phenomenon may be a novel
polymorphism in the principal arginine transporter that
accounts, at least in part, for the link between endothelial
dysfunction, L-arginine, nitric oxide metabolism, and
essential hypertension.13

Natural history of endothelial
dysfunction
The development and progression of atherosclerosis is a
result of inflammatory processes including expression of
markers of endothelial activation.14 For example, vascular
cell adhesion molecule-1 facilitates the binding of monocytes
and T-lymphocytes to vessel walls. A variety of cytokines
and growth factors, such as macrophage colony-stimulating
factor-1 (M-CSF-1) and transforming growth factor (TGF)-α
and TGF-β, are released from inflammatory lesions, recruit
additional leukocytes, and stimulate proliferation of vascular
smooth muscle cells.

As discussed elsewhere, the presence of monocytes
in the intima is a characteristic of the early stages of
plaque formation.15–18 Chemoattractant substances such as
monocyte chemoattractant protein-1 (MCP-1) are generated
by vascular inflammation and promote infiltration of
monocytes into the intima. After infiltrating the vascular
endothelium, monocytes are transformed into tissue
macrophages, which engulf lipid particles and become
“foam cells”. Accumulation of foam cells gives rise to a
visible fatty streak on the luminal surface of arteries.
Work by the author and his associates first established an
obligatory role of angiotensin II (Ang II) in mediating the
cascade of initiating events leading to the appearance of
foam cells.15–18

Endothelial dysfunction involves accumulation of lipids,
inflammation, and proliferation of vascular smooth muscle
cells. Recruitment of inflammatory cells, proliferation of
vascular smooth muscle, and accumulation of lipids by
foam cells all contribute to thickening of the intima and
the creation of an atherosclerotic plaque. Atherosclerosis
occurs preferentially in areas of turbulent blood flow and
low shear stress.19

Role of the renin-angiotensin-
aldosterone system (RAAS)
in endothelial dysfunction
The renin-angiotensin-aldosterone system (RAAS) has a
well-established role in the regulation of sodium levels, fluid
balance, and blood pressure (BP). Emerging evidence suggests
that this system is also involved in the pathophysiology of
type 2 diabetes mellitus and obesity.20–26

The classical view of the RAAS holds that the octapeptide
Ang II is the terminal effector in this endocrine signaling
pathway, and that upon binding to Ang II type 1 (AT1)
receptors, vasoconstriction and sodium and water retention
occur, along with mitogenic and proliferative effects on
vascular endothelial and smooth muscle cells.27 There is
evidence that Ang II is involved in pathologic inflammation,
and that it increases oxidative stress by regulating nicotinamide
adenine dinucleotide phosphate (NADPH) levels, the principal
source of reactive oxygen species (ROS) in the vasculature.
Ang II also accelerates senescence of endothelial progenitor
cells (EPCs).28 Senescence of EPCs is accelerated in patients
with essential hypertension, and patients with CAD have
fewer EPCs in peripheral blood.29

A seminal study assessing the role of Ang II in the
development of atherosclerosis in primates first documented a
critical contribution of the renin-angiotensin system in the origin
of fatty streak formation. In this study,30 the administration of
the angiotensin receptor blocker (ARB), losartan, prevented the
development of aortic fatty streak formation by a mechanism
independent of BP. The central role of Ang II in endothelial
dysfunction and atherosclerotic plaque formation is illustrated
in Figure 1. Later studies in knockout mice confirm that the
AT₁ receptor is involved in atherosclerosis. Apolipoprotein
E knockout mice (ApoE−/−) have impaired endothelium-
dependent vasodilation, significantly higher superoxide radical
release rates, and develop marked atherosclerotic lesions when
fed a high cholesterol diet. In contrast, AT₁−/− mice have greatly
reduced vascular oxidative stress, endothelial dysfunction,
and atherosclerotic lesion formation irrespective of BP and
plasma cholesterol levels. When ApoE−/− mice were crossbred
with AT₁ receptor-deficient mice, the resulting progeny (ApoE−/−, AT₁−/−) had significantly lower BP levels and superoxide release rates than ApoE−/− mice and did not develop atherosclerosis. These studies suggest a fundamental role of AT₁ receptor activation in atherogenesis. In the pursuit of the mechanism accounting for the actions of Ang II in atherogenesis, we found that early activation of monocytes occurred through upregulation of the bone marrow renin-angiotensin system, whereby hypercholesterolemia stimulates the expression of bone marrow CD11b+ receptors in monocytes.

Over the last decade, it has become clear that the classical view of the RAAS is in need of revision. An additional RAAS effector that counterbalances the biological actions of Ang II has been isolated and characterized. This additional effector, the heptapeptide Ang-(1–7), is a fragment produced by the hydrolysis of Ang I by several tissue-specific endopeptidases (prolyl oligopeptidase and thimet oligopeptidase in vascular endothelial and smooth muscle cells, and neprilysin in kidney cells) that bind to the G-protein-coupled mas receptor. More recently, it has been shown that Ang-(1–7) is also produced by a homolog of angiotensin-converting enzyme (ACE), known as angiotensin-converting enzyme 2 (ACE2). ACE2 is a membrane-bound metallopeptidase that has a high specificity for Ang II and acts to regulate the balance between Ang II and the ACE2/Ang(1–7) axes of the RAAS. This counter-regulatory balance exists between the two arms of the RAAS, as illustrated in Figure 2.

As proposed by Ferrario, under normal physiological conditions, both the ACE/Ang II and the ACE2/Ang(1–7) axes of the RAAS strike a balance between proliferative and antiproliferative effects. However, when a physiological imbalance occurs as a result of a pathological process, such as increased activity of the ACE/Ang II/AT₁ receptor axis, the failure of compensation by the opposing axis favors hypertension and consequent cardiovascular remodeling.

Drugs that target and block the effects of Ang II would be expected to prevent or reverse endothelial dysfunction and improve long-term morbidity and mortality outcomes in a broad spectrum of patients. This is, indeed, the case. Three classes of agents, ACE inhibitors, ARBs, and, most recently, direct renin inhibitors (DRIs), have been developed to specifically target the RAAS. Most experience has been gained with ACE inhibitors and ARBs, which are widely approved and used for the treatment of hypertension and prevention of CVD, although a recent study showed that aliskiren resulted in striking reductions of atherosclerosis in fat-fed low-density lipoprotein (LDL) receptor-deficient (LDLr−/−) mice.

ARBs selectively target the AT₁ receptor and have a well-established role in the management of hypertension. Drugs in this class have been shown to improve outcomes in patients with hypertension, ventricular hypertrophy, diabetes mellitus, renal disease, and congestive heart failure.
Within the ARB class, olmesartan medoxomil is a long-acting Ang II antagonist approved for the treatment of mild to severe hypertension, alone or in combination with other agents. In addition to producing sustained reductions in BP, the drug corrects the underlying defects that lead to endothelial dysfunction in animal models of CVD, and in patients with CVD or hypertension. Moreover, the beneficial effects of the drug on endothelial dysfunction have been shown to complement those of the 3-hydroxy-3-methyl-glutaryl coenzyme A (HMG-CoA) reductase inhibitors. Intriguing evidence suggests that olmesartan upregulates cardiac and vascular expression of ACE2, which leads to greater conversion of Ang II into the vasodilator and anti-proliferative peptide Ang-(1–7). The purpose of this paper is to review the extensive literature on the effects of olmesartan medoxomil on endothelial function, both in humans and animal models.

**Studies in humans**

Olmesartan medoxomil produces broad-based improvements in endothelial dysfunction in patients with hypertension. The drug reduces vascular micro-inflammation, decreases the volume of large atherosclerotic plaques, improves endothelium-dependent relaxation, and restores normal resistance vessel morphology. An overview of beneficial effects of olmesartan medoxomil on endothelial function in humans is provided in Table 2.

**Effect of olmesartan medoxomil on markers of vascular inflammation: the EUTOPIA study**

Olmesartan medoxomil significantly reduced vascular inflammation in patients with hypertension in the European Trial on Olmesartan and Pravastatin in Inflammation and Atherosclerosis (EUTOPIA) study. EUTOPIA was a randomized, placebo-controlled, multicenter study in 199 patients with hypertension and vascular micro-inflammation. Vascular micro-inflammation was defined as the presence of any diagnosed atherosclerotic disease (eg, coronary or peripheral arterial disease), type 2 diabetes mellitus, and/or an LDL-cholesterol level between 3.89 and 6.48 mmol/L (152–253 mg/dL). In addition to hypertension (seated diastolic BP [SeDBP] of 95 to 110 mmHg), eligible patients were required to have a high-sensitivity C-reactive protein (hsCRP) concentration >3 mg/L but ≤20 mg/L, and detectable serum levels of interleukin-6 (IL-6) and intercellular adhesion molecule-1 (ICAM-1). Patients were randomized to 12 weeks of treatment with olmesartan medoxomil 20 mg/day.

---

**Table 1 Ang-(1–7) in cardiovascular disease and hypertension**

**Animal studies**

- Blockade of Ang-(1–7) dose-dependently ↑ arterial BP in salt-restricted rats
- Intracerebroventricular administration of anti-Ang-(1–7) antibodies ↑ BP in rats
- Ang-(1–7) augments baroreceptor reflex control of HR at the nucleus of the solitary tract
- Ang-(1–7) is cardioprotective in heart failure in rats induced by Ang II
- Ang-(1–7) protects against ischemic injury and arrhythmia in isolated rat hearts
- Ang-(1–7) dilates afferent arterioles, ↑ GFR and induces natriuresis and diuresis
- Ang-(1–7) ↓ neointimal proliferation after vascular injury in rat carotid arteries
- Ang-(1–7) ↓ Ang II-induced protein synthesis in cardiomyocytes
- Ang-(1–7) ↓ myocyte surface area after MI induced by coronary artery ligation in rats
- Olmesartan, but not atenolol, ↑ Ang I, Ang II, and Ang-(1–7) in SHR
- Olmesartan, but not atenolol or hydralazine, ↑ ACE2 and Ang-(1–7) and improved remodeling of the aorta in SHR
- Olmesartan and losartan ↑ ACE2 mRNA in non-infarcted ventricular tissue in rats
- Olmesartan ↑ cardiac ACE2 expression in stroke-prone SHR
- Olmesartan ↑ ACE2 immunostaining in neointima of injured carotid arteries in SHR
- Cardiac ACE2 metabolizes Ang II to Ang-(1–7) in the hearts of hypertensive rats

**Human studies**

- Plasma and urinary Ang-(1–7) levels are ↓ in untreated hypertensive patients
- Plasma and urinary Ang-(1–7) ↑ when BP ↓ with agents that modulate the RAAS

**Abbreviations:** ACE, angiotensin-converting enzyme; Ang, angiotensin; BP, blood pressure; GFR, glomerular filtration rate; HR, hypertensive rats; MI, myocardial infarction; mRNA, messenger ribonucleic acid; RAAS, renin-angiotensin-aldosterone system; SHR, spontaneously hypertensive rats.
Olmesartan medoxomil improves endothelial dysfunction

or placebo. Hydrochlorothiazide 12.5 or 25 mg/day could be added for patients whose SeDBP remained ≥90 mmHg. After 6 weeks of double-blind treatment, all patients started treatment with the HMG-CoA reductase inhibitor pravastatin 20 mg/day and continued treatment for the remainder of the study. The final full analysis set comprised 100 patients in the olmesartan medoxomil and 99 patients in the placebo treatment groups.

The primary outcome was the impact of olmesartan medoxomil (alone or in combination with pravastatin) on a panel of anti-inflammatory measures: hsCRP, high sensitivity tumor necrosis factor-α (hsTNF-α), IL-6, ICAM-1, and MCP-1. Olmesartan medoxomil produced significant reductions from baseline in hsCRP, hsTNF-α, IL-6, and MCP-1 (all comparisons p < 0.05 vs baseline), but not ICAM-1, after 6 and 12 weeks of treatment. In contrast, there were no statistically significant reductions from baseline in any inflammatory markers in patients treated with placebo, with the exception of IL-6 at Week 6 (but not at Week 12). The difference in hsTNF-α between olmesartan medoxomil and placebo recipients at Week 12 was statistically significant.

There were no significant changes in the serum lipid profile between baseline and Week 6 in recipients of olmesartan medoxomil or placebo. As expected, the addition of pravastatin produced significant reductions in total cholesterol and LDL cholesterol between Week 6 and Week 12 of treatment in both groups. Systolic BP (SBP)/DBP decreased significantly compared with baseline in both treatment groups, with significantly greater reductions achieved with olmesartan medoxomil than placebo at all time points with the exception of SBP at Week 12.

**Effect of olmesartan medoxomil on EPCs in patients with type 2 diabetes mellitus**

ARBs increase the number of regenerative EPCs in peripheral blood of patients with type 2 diabetes mellitus, a condition associated with endothelial dysfunction. In a randomized, double-blind, placebo-controlled study, before treatment with olmesartan medoxomil, the number of EPCs was significantly lower in 18 patients with type 2 diabetes mellitus and hypertension compared with 38 age-matched healthy volunteers. After 12 weeks of treatment with olmesartan medoxomil 40 mg/day (n = 9), the number of circulating EPCs increased significantly in patients with type 2 diabetes mellitus (from 231 to 465 per high power field width, p < 0.05 vs placebo). There was no change in the number of CD34+ hematopoietic progenitor cells after treatment with olmesartan medoxomil.

---

**Abbreviations:** ACE, angiotensin-converting enzyme; Ang, angiotensin; AT1R, angiotensin type 1 receptor; AT2R, angiotensin type 2 receptor; NEP, neprilysin; POP, prolyl oligopeptidase; TOP, thimet oligopeptidase.
The results of the Multicentre, Olmesartan, atherosclerosis Regression Evaluation (MORE) study suggest that olmesartan medoxomil reduces the volume of larger atherosclerotic plaques in patients with hypertension, independent of BP reduction. After 2 years of treatment, there was no statistically significant difference between treatment groups in the IMT of the common carotid artery (CC-IMT), as determined by 2-dimensional ultrasound, the primary efficacy outcome in the trial. Among patients randomized to olmesartan medoxomil (20–40 mg/day, n = 78), the mean change in CC-IMT was –0.090 mm, and among those randomized to atenolol (50–100 mg/day, n = 77), the mean reduction in CC-IMT was –0.082 mm. The overall mean change in plaque volume, as determined by 3-dimensional ultrasound, was –4.4 μL in patients randomized to olmesartan medoxomil and +0.1 μL in patients randomized to atenolol, although the difference was not statistically significant. However, the reduction in plaque volume was significantly greater in recipients of olmesartan medoxomil (–11.5 μL) than atenolol (+0.6 μL) when the analysis was restricted to patients with a baseline plaque volume greater than or equal to the median value (33.7 μL). There was no statistically significant difference in mean SBP/DBP at baseline (158/96 vs 157/96 mmHg, respectively) or in the mean reduction in SBP/DBP after 2 years of treatment (–25/–15 vs –22/–14 mmHg, respectively) between patients randomized to olmesartan medoxomil or atenolol. There was a higher proportion of men (73% vs 50% in the olmesartan medoxomil group), more current smokers (38% vs 31% in the olmesartan medoxomil group), and more patients with a history of CVD (14% vs 9% in the olmesartan medoxomil group) among those randomized to atenolol. It is possible that technical limitations in terms of resolving differences in the volume of small plaques by 3-dimensional ultrasound sonography accounted for the failure of observing differences in plaque regression.

### Effect of olmesartan medoxomil on endothelium-dependent vasodilation

Olmesartan medoxomil improved endothelium-dependent coronary artery dilation in patients with hypertension in a randomized study in 26 patients with untreated hypertension (BP > 140/90 mmHg). After 12 weeks, the mean decrease in SBP was similar in patients randomized to olmesartan medoxomil (n = 13; –28.7 mmHg) or amlodipine (n = 13; –26.7 mmHg). However, there was a significant increase of the delta change in corrected myocardial blood flow (before vs after treatment p < 0.001) and a significant decrease in the ΔCVR (before vs after treatment p < 0.01) from rest after a cold pressor test as measured by positron emission tomography among patients treated with olmesartan medoxomil. In contrast, 12 weeks of treatment with amlodipine had no effect on either parameter.
Among patients treated with olmesartan medoxomil, there was also a significant negative correlation between changes in serum superoxide dismutase (SOD) activity and CVR.58

The study by Naya et al66 provides evidence that treatment with an ARB (olmesartan medoxomil) but not a calcium channel blocker (amlodipine) has a salutary effect on the coronary microcirculation and improves endothelium-dependent coronary dilation independent of BP lowering.66

**Effect of olmesartan medoxomil on vessel morphology: the VIOS study**67,68

The objective of VIOS (Vascular Improvement with Olmesartan medoxomil Study) was to examine the impact of olmesartan medoxomil on vascular remodeling in nondiabetic patients with stage 1 hypertension as evaluated in the office setting. A total of 100 patients were randomized to 12 months of treatment with either olmesartan medoxomil 20 mg/day or atenolol 50 mg/day. The dosage of either agent was doubled to achieve optimal BP control, and hydrochlorothiazide, amlodipine, or hydralazine could be added to ongoing therapy.57 As a result of this study design, the mean reduction in BP was not statistically different between treatment groups at Week 12, 28, or 52 of treatment.

The mean augmentation index (augmentation pressure/pulse pressure), a surrogate measure of vascular compliance, decreased significantly between baseline and the end of treatment in olmesartan medoxomil recipients, but was unchanged among atenolol recipients. Significant decreases in central aortic pressure were also documented, with no differences between the two treatment groups.57 On the other hand, prior to initiation of the treatment period, measures of central aortic pressure in the overall group of patients averaged 131 ± 16 mmHg, a value that is within the range established for prehypertension by the Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7) classification.

Before initiation of treatment, the wall width (WW), media cross sectional area (MCSA), and wall-to-lumen (W/L) ratio of resistance arteries in gluteal subcutaneous biopsies were all significantly higher in a subgroup of 55 patients with hypertension than in a parallel group of 11 normotensive volunteers.67 At baseline, these dimensions were similar in hypertensive patients randomized to olmesartan medoxomil (n = 27) or atenolol (n = 22); however, after 12 months of treatment with olmesartan medoxomil, but not with atenolol, there was a significant decrease in all of these arteriolar dimensions (p < 0.01 vs baseline). The mean W/L ratio in arteries from patients receiving olmesartan medoxomil therapy was significantly reduced after 1 year of treatment compared with baseline (11.1% ± 0.5 vs 14.9% ± 0.8, respectively; p < 0.01), whereas the mean W/L ratio in arteries from atenolol-treated patients was not significantly decreased (15.5% vs 16.0%, respectively; p > 0.05). The mean W/L ratio in olmesartan medoxomil recipients (11.1%) was similar to that in normotensive controls (11.0%) after 1 year of treatment. The VIOS trial demonstrated that 1 year of treatment with olmesartan medoxomil restored the normal resistance vessel morphology in stage 1 hypertension independent of BP lowering.67

**Studies in animals**

Olmesartan has been shown to reduce oxidative stress and endothelial inflammation, and to prevent or reverse the formation of atherosclerotic lesions and vascular remodeling processes in a variety of animal models of atherosclerosis. The drug has also been shown to have renoprotective effects in animal models of kidney disease and retinoprotective effects in an animal model of retinopathy.

**Diabetes, insulin resistance, and metabolic syndrome animal models**

Mice fed a high fat diet have increased oxidative stress in cardiac, vascular, and hepatic tissue.69 Olmesartan 5 mg/kg/day markedly suppressed cardiac inflammation and fibrosis, ameliorated endothelial dysfunction, and retarded vascular remodeling in an animal model of diabetes.69 The drug also prevented hepatic steatosis, halted progression of hepatic fibrosis, and suppressed the disruption in vascular endothelial NO synthase (eNOS) dimer. The beneficial effects of olmesartan were associated with a decrease in apoptosis signal regulating kinase-1 (ASK-1). ROS activate ASK-1, which, in turn, has been shown to be involved in Ang II-induced cardiac hypertrophy and remodeling.70 Interestingly, hydralazine lowered BP in the same strain of diabetic mice, but, unlike olmesartan, had no effect on cardiac remodeling, vascular endothelial function, or hepatic fibrosis.69 Moreover, olmesartan had no effect on any of these parameters in ASK-1-deficient mice. The results of the study suggest that Ang II plays a central role in cardiovascular remodeling and endothelial dysfunction in the setting of diabetes, and that olmesartan prevents vascular remodeling, in part, by attenuating the generation of ROS.69

**Models of hypertension**

Treatment with olmesartan 15 mg/kg/day and enalapril 25 mg/kg/day from age 8 weeks to age 12 weeks significantly decreased the left ventricular weight/body weight ratio and normalized cardiac collagen content and the media:lumen
ratio in spontaneously hypertensive rats (SHR). Significant improvements in aortic collagen content were also obtained with a lower dose of olmesartan (1 mg/kg/day) but not enalapril (2 mg/kg/day).71

In another study in SHR that served as the rationale for the VIOS study (see above67), olmesartan 10 mg/kg/day produced a greater reduction in the arteriolar W/L ratio than atenolol after 8 weeks of treatment, despite similar reductions in BP.57 Treatment with olmesartan significantly increased lumen diameter and significantly decreased WW and the W/L ratio of mesenteric arteries compared with control SHR. The improvement in W/L ratio was also significantly greater than that achieved with atenolol. Treatment with atenolol also decreased WW and the W/L ratio but did not significantly alter the lumen diameter. The lumen diameter was significantly greater in olmesartan-treated animals than in control rats when exposed to luminal pressures ranging from 20 mmHg to 100 mmHg. Atenolol-treated animals did not differ from control animals in this respect. The heart weight:body weight ratio, a measure of cardiac hypertrophy, was significantly decreased in animals treated with olmesartan, but not with atenolol. The results of this study are consistent with those of the 1-year-long VIOS trial in humans and demonstrate that treatment with olmesartan can restore resistance vessel morphology after pathological changes have occurred.

Olmesartan reduced the production of ROS, suppressed tissue infiltration of macrophages, and prevented ventricular hypertrophy and fibrosis in hypertensive Dahl salt-sensitive rats with advanced heart failure who were administered olmesartan from age 17 weeks to age 20 weeks.72 The addition of olmesartan 0.3 mg/kg/day to ongoing treatment with an ACE inhibitor (temocapril 0.2 mg/kg/day) produced further reductions in 4-hydroxy-2-nonenal-modified protein levels, a lipid peroxidation product and marker of ROS generation, in addition to those produced by the ACE inhibitor alone.72 The beneficial effects of olmesartan in these models may be attributable, in part, to upregulation of ACE2, which results in increased Ang-(1–7) levels.53,61 For example, Yokoyama et al.57 detected elevated concentrations of Ang I, Ang II, angiotensin-(1–7), elevated serum aldosterone, and reduced AT-1a receptor mRNA.58 Blockade of AT-1a receptors with an ARB (losartan or olmesartan) for 28 days attenuated cardiac hypertrophy, reduced aldosterone levels, and was associated with further increases in Ang levels. Olmesartan improved contractility; losartan did not. Both ARBs produced a three-fold increase in ACE2 mRNA levels and downregulated AT-1a receptor expression in non-infarcted ventricular tissue.53 The beneficial effects of ARB treatment in this model were independent of effects of BP and infarct size. The results suggest that upregulation of ACE2 and increased conversion of Ang II to Ang-(1–7) counterbalances the vasopressor effects resulting from the ACE-mediated conversion of Ang I to Ang II.

Animal models of atherosclerosis

Hypercholesterolemia-induced atherosclerosis in cynomolgus monkeys (Macaca fascicularis) is similar to that in humans. When maintained on a high cholesterol diet, monkeys develop fatty aortic streaks that can be detected by intravascular ultrasonography; increased levels of TGF-β1, ICAM-1, and M-CSF; and accumulations of macrophages in the intima, as evidenced by increased binding of specific antibodies in aortic cross sections.50,73,74 Treatment with olmesartan 10 mg/kg/day maintained TGF-β1, ICAM-1, and M-CSF levels similar to those in control monkeys fed a normal diet; significantly reduced the accumulation of macrophages in the intima; significantly reduced the extent of lipid deposition in the aorta; and significantly reduced the atherosclerotic intima area, and intima area:media ratio of the aorta.
The combination of olmesartan and pravastatin improved endothelial function in salt-loaded Dahl salt-sensitive hypertensive rats. Vascular endothelium-dependent relaxation to acetylcholine, coronary arterial remodeling, and eNOS activity were all significantly improved after 4 weeks of treatment with olmesartan 0.5 mg/kg/day plus pravastatin 100 mg/kg/day. Olmesartan prevented disruption of vascular eNOS dimers and downregulation of dihydrofolate reductase to a greater extent than pravastatin; conversely, Akt phosphorylation was enhanced by pravastatin, but not by olmesartan medoxomil.

Studies in ApoE knockout mice
ApoE knockout mice are predisposed to develop atherosclerosis. When fed a high cholesterol diet, these mice develop marked atherosclerotic lesions in the proximal aorta and exhibit signs of oxidative stress (increased staining for NADPH oxidase, an enzyme that produces ROS). At a dose of 3 mg/kg/day, olmesartan significantly inhibited NADPH oxidase activity, decreased superoxide production, reduced the formation of atherosclerotic lesions, and inhibited lipid deposition. In another study in which apoE knockout mice were fed either a high cholesterol or normal diet for 25 weeks, treatment with olmesartan 10 mg/kg/day produced significant reductions in the surface area of aortic lesions and the cross-sectional area of aortic valves in both groups of mice.

Renoprotective effects
Olmesartan has been shown to significantly improve urinary protein and β2-microglobulin excretion, ameliorate glomerular sclerosis and tubulointerstitial injury, and to significantly reduce staining for TGF-β, vascular endothelial growth factor, and type IV collagen in glomeruli of diabetic rats. SHR have enhanced intrarenal angiotensinogen production that contributes to increased Ang II levels and leads to hypertension and renal injury. Olmesartan reduced the urinary excretion rate of total protein, prevented glomerular sclerosis, interstitial expansion, and reduced the numbers of monocytes/macrophages in the interstitium or glomeruli of SHR. The drug also reduced angiotensinogen mRNA and protein levels in the kidney cortex, as measured by real-time PCR. In corpulent SHR, treatment with the drug significantly reduced BP and kidney pentosidine content (which is correlated with proteinuria) and reduced histologic renal damage and proteinuria. In another study in SHR, olmesartan, but not nifedipine or atenolol, significantly reduced proteinuria and prevented glomerular and tubulointerstitial damage (mesangial activation, podocyte

In a subsequent 12-month study in the same monkey model of atherosclerosis, treatment with olmesartan 3 mg/kg/day significantly reduced serum levels of MCP-1, an inflammatory marker, compared with cholesterol-fed monkeys; significantly reduced the intima volume:total volume ratio of the thoracic aorta; and produced significant regression in the size of existing atherosclerotic lesions as indicated by the atherosclerotic area:total surface area of the aorta. Importantly, all of the effects attributable to olmesartan in these studies occurred without significant effects on BP or total cholesterol, LDL-cholesterol, or high-density lipoprotein-cholesterol levels.

In Watanabe heritable hyperlipidemic rabbits, the combination of olmesartan and pravastatin had complementary inhibitory effects on atherosclerotic lesions. Olmesartan 0.5 mg/kg/day and pravastatin 25 mg/kg/day produced significant reductions in BP and blood cholesterol levels that were accompanied by significant reductions in the surface area and thickness of atherosclerotic lesions and in aortic cholesterol content. The anti-atherosclerotic effects of the two drugs in combination were significantly greater than those produced by monotherapy with either agent. Immunohistochemical staining of cross sections of aortic tissue showed that both drugs inhibited macrophage infiltration, that pravastatin inhibited lipid deposition, and that olmesartan reduced MCP-1 expression and formation of Nε-(carboxymethyl)lysine protein adducts, a marker of oxidative stress.

The combination of olmesartan and pravastatin produced additive improvements in left ventricular remodeling in rats with MI induced by ligation of the left anterior descending coronary artery. When administered alone, both drugs decreased cardiomyocyte size; however, the magnitude of the improvement was greater when the two drugs were co-administered. Treatment with the two drugs also downregulated left ventricular atrial natriuretic peptide mRNA. The effects on cardiomyocyte hypertrophy were dose-dependent.

The combination of olmesartan and pravastatin also significantly reduced the progression of atherosclerosis in ApoE*3Leiden transgenic mice, which develop a human-like lipoprotein profile when fed a cholesterol-rich diet. The number and extent of atherogenic lesions and the number of macrophages and T lymphocytes per cross section was significantly reduced in mice treated with the combination compared with controls. When administered alone or in combination with pravastatin, olmesartan reduced the quantity of macrophages in lesions compared with control.
injury, tubulointerstitial injury, and inflammatory cell infiltration). The drug also selectively prevented abnormal iron deposition in the interstitium, corrected chronic hypoxia, reduced expression of heme oxygenase and p47phox (a subunit of NADPH oxidase), and inhibited pentosidine formation in this animal model. The unique renoprotective properties of olmesartan were independent of BP reductions and appeared to be attributable to decreased oxidative stress, correction of chronic hypoxia, and inhibition of advanced glycation end product formation, and of abnormal iron deposition.83

Retinoprotective effects
Olmesartan has been shown to have beneficial effects in several animal models of early and late stage retinopathy. The drug prevented elongation of oscillatory potential peaks in a dose-dependent manner in diabetic stroke-prone SHR. In mice with oxygen-induced retinopathy, the drug significantly prevented retinal neovascularization at a dosage of 1 mg/kg/day. Plasma concentrations of olmesartan in these experiments were comparable to the in vitro IC50 value of the AT1 receptor.84

Miscellaneous effects of olmesartan
Olmesartan has been shown to have antiproliferative effects in animal models of CVD. Olmesartan significantly reduced endothelial inflammatory events in a mouse model of vascular injury that involves the placement of a polyethylene cuff around the femoral artery.85 At a dose of 3 mg/kg/day, the drug significantly prevented retinal neovascularization and vascular smooth muscle proliferation. In another study that used the same model of endothelial inflammation, olmesartan reduced the number of bromodeoxyuridine-positive vascular smooth muscle cells present in the media and neointima, and prevented phosphorylation of extracellular signal-regulated kinase (ERK, an enzyme associated with progression of fibrosis and cell proliferation) and signal transducer and activator of transcription, all of which indicate that cell division (fibrosis and cell proliferation) and signal transducer and activator of transcription, all of which indicate that cell division in inflammatory lesions is attenuated by olmesartan.86 Treatment with the drug also significantly reduced the rate of DNA synthesis in vascular smooth muscle cells in vitro, as indicated by incorporation of [3H]-thymidine, and blocked activation of ERK.87

Endothelium-dependent relaxation of the aorta of 12-month-old Wistar-Kyoto rats is markedly impaired compared with those of 3-month-old rats.88 Thus, aged rats serve as a model for age-related endothelial dysfunction. Tiron, a superoxide scavenger, partially improved endothelium-dependent relaxation in this model, suggesting involvement of superoxide. Treatment of aged rats with olmesartan 5 mg/kg/day for 2 weeks significantly reduced superoxide production. Endothelium-dependent relaxation also improved in aged rats after long-term treatment with olmesartan or temocapril, but not cervastatin or hydralazine. Indomethacin also improved endothelium-dependent relaxation when administered alone, but not after treatment with olmesartan or temocapril. Cyclooxygenase (COX)-2 protein expression and superoxide production were increased in the aortas of aged rats, but were attenuated by olmesartan and temocapril. These results suggest that inhibition of the RAAS corrects age-related endothelial dysfunction, in part, by inhibiting synthesis of COX-2-derived vasoconstricting factors and superoxide anions.88

Summary and conclusions
Endothelial dysfunction is the common link between CVD risk factors and is one of the earliest events in the cascade of changes that results in target organ damage in patients with hypertension. It has been shown that coronary artery endothelial dysfunction is associated with increased CVD risk, and increased carotid artery IMT is predictive of MI and stroke. The large arteries in hypertensive patients are thicker and stiffer than those in normotensive individuals; thus, reversal of the underlying processes that cause these structural changes and normalization of vessel wall dimensions should be a goal of antihypertensive therapy.

Ang II is a potent vasoconstrictor, which promotes sodium and fluid retention and has mitogenic and proliferative effects on vascular endothelial and smooth muscle cells. Under normal physiological conditions, these effects are counterbalanced by Ang-(1–7). In contrast, under pathological conditions, the effects of Ang II become predominant and endothelial dysfunction results. ARBs correct the pathological imbalance in the RAAS, in part, by augmenting the activity of the ACE2/Ang-(1–7) axis.42,54

While it would be expected that all Ang II receptor blockers share similar characteristics in terms of the mechanisms of action, both past and emerging data suggest that this may not be the case. A systematic review, performed to identify the factors that determine the antihypertensive activity of the ARBs using 24-hour ambulatory BP monitoring data from 35 studies, showed the greatest reductions in both SBP and DBP being seen with olmesartan medoxomil.89 Studies of the pharmacological characteristics of olmesartan provide support for the clinical findings. In vitro studies of guinea pig aorta showed that olmesartan inhibited Ang II-induced contraction with a potency 160, 3.4, and 1.2 times greater than...
Olmesartan medoxomil improves endothelial dysfunction

MORE study. However, olmesartan medoxomil did produce significant reductions in the volume of large atherosclerotic plaques compared with atenolol in patients enrolled in this trial. In the VIOS study, 1 year of treatment with olmesartan medoxomil restored the normal morphology of resistance vessels in patients with hypertension. WW, MCSA, and the W/L ratio in olmesartan medoxomil-treated patients was restored to the same dimensions as that in normotensive controls at the end of the study. Clinical studies in patients have also shown that olmesartan medoxomil significantly increased the number of regenerative EPCs in the peripheral circulation and improves endothelium-dependent relaxation. Importantly, the positive benefits of olmesartan medoxomil on improving endothelial dysfunction appear to be independent of BP lowering.
