Assessment of tear film in subjects with a high body mass index

Saud A Alanazi
Cornea Research Chair, Department of Optometry, College of Applied Medical Sciences, King Saud University, Riyadh, 11433, Saudi Arabia

Purpose: The aim of the study was to assess the tear film in subjects with a high body mass index (BMI).

Methods: Twenty male subjects aged 23–42 years (mean ± standard deviation = 31.3 ± 5.7 years) with a high BMI [median (interquartile range) = 31.8 (5.2) kg/m²] were recruited. An age-matched control group of twenty male subjects aged 22–38 years with a normal BMI [20.5 (2.8) kg/m²] also participated in the study.

Results: There were significant (Kolmogorov-Smirnov test; P < 0.05) differences in the BMI, non-invasive tear break-up time (NITBUT), and tear ferning (TF) scores between the study and control groups. There were some differences in the ocular surface disease index (OSDI), tear meniscus height (TMH), and phenol red thread (PRT) scores between the study and control groups, but these differences were not significant (Kolmogorov-Smirnov test; P > 0.05). For the study group, the NITBUT and TF tests mean scores showed a dry eye condition (8.5±2.8 s and 2.0±1.1, respectively). However, these two tests showed a normal eye condition within the control group (14.7±2.8 s and 0.7±0.6, respectively). The TMH score had strong correlations with the NITBUT (r = 0.711; P = 0.001) and PRT scores (r = 0.566; P = 0.009) and strong negative correlations with age (r = -0.503; P = 0.024) and the OSDI scores (r = -0.520; P = 0.018). The TF score had a strong correlation with age (r = 0.579; P = 0.007) and strong negative correlations with the scores from the NITBUT (r = -0.525; P = 0.018), TMH (r = -0.575; P = 0.008), and PRT (r = -0.773; P = 0.001) tests.

Conclusion: The acquired data suggest a high BMI has an effect on the quality of tears. The quality of tears seems to be lower in subjects with a high BMI compared with normal subjects. On the other hand, the tear volume in subjects with a high BMI was just as high and adequate as for normal eye subjects.

Keywords: body mass index, tear film, dry eye, tear ferning test, correlation, tear meniscus height

Introduction

Ocular health is largely dependent on the tear film, as it acts as a surface in order to refract light entering the eye, as well as moisturizing, and protecting the cornea. A model has been proposed for the structure of the tear film that is composed of three phases, namely, the mucin, aqueous, and lipid layers. The mucin layer, secreted by goblet cells, covers the ocular surface and lowers epithelial cells’ hydrophobicity. The aqueous layer, secreted by the Krause and Wolfring glands, lubricates the cornea, provides the nutrients that are needed for the ocular surface, keeps the osmolarity balanced, and acts as an antimicrobial barrier against microorganism infections. The lipid layer, secreted by the meibomian glands, reduces the evaporation and overspill of tears. However, the structure, dynamics, and function of the
tear film is very complex in reality. Tear film instability results in several vision problems where dry eye syndrome is common.

Dry eye causes many uncomfortable symptoms that affect the quality of life of around 20% of the global population. Therefore, eye dryness has to be managed as early as possible. Dry eye symptoms are very common, mainly due to dysfunction of the meibomian gland. The main cause of dry eye symptoms is an alteration in either tear production or tear evaporation, or both. Several tests can be used to assess the tear film in terms of the volume and quality of tears. However, the correlations between these tests are very limited and a combination of several tests should be used to obtain more reliable results. Tear volume can be assessed by the use of phenol red thread (PRT), tear meniscus height (TMH), and tear evaporation rate tests, for example. On the other hand, the quality of tears can be assessed using non-invasive tear break-up time (NITBUT), tear ferning (TF), and osmolarity tests, for example. In addition, dry eye questionnaires (eg, the ocular surface disease index, OSDI) can be used as a useful, quick, and efficient tool to detect the discomfort associated with a dry eye condition.

Obesity is becoming a major concern worldwide. Body mass index (BMI), which is the ratio between weight and height, can be used as a simple, efficient, and low-cost tool to measure fitness. A high BMI could be a risk factor for various disorders such as type-2 diabetes, coronary heart disease, hypertension, stroke, and premature mortality, as a result of sleep apnea. Several factors (eg, culture) are contributing to the increased level of obesity, leading to a general health issue. It is important to increase awareness about obesity and its association with various illnesses. In the current study, the link between dry eye symptoms and BMI was investigated using a combination of tests that can determine both the quantity and quality of tears. To the best of our knowledge, this study is the first to utilize the tear ferning test to assess the tear film within subjects having a BMI. Recently, various studies showed that TF tests along with other dry diagnostic tests can be used efficiently to assess the ocular tear film.

Materials and methods

Subjects

Twenty male subjects aged 23–42 years (mean ± standard deviation =31.3±5.7 years) with a high BMI [median (interquartile range) =31.8 (5.2) kg/m²] were recruited. An age-matched control group of twenty male subjects aged 22–38 years (30.2±4.9 years) with a normal BMI [20.5 (2.8) kg/m²] also participated in the study. Subjects with thyroid disorders, a high cholesterol level (above 4 mmol/L), vitamin A and D deficiencies, hypertension, anaemia, diabetes, who were smokers, who a history of ocular surgery, and who wore contact lenses were excluded. The subjects were tested at King Khalid Hospital, Riyadh between 9:30 and 11:30 am by the same examiner. Ethical approval was obtained from the College of Applied Medical Science Ethics Committee, King Saud University, and the subjects were treated based on the Declaration of Helsinki. Written informed consent was obtained from each subject before conducting the study. The OSDI sheet was completed first, followed by the NITBUT, TMH, PRT, and TF tests. The tests were carried out on the right eye of each subject and a 10 min gap was allowed between the tests.

BMI

The subjects were classified based on their BMI scores as underweight (15–19.9 Kg/m²), normal weight (20–24.9 Kg/m²), overweight (25–29.9 Kg/m²), first class obese (30–34.9 Kg/m²), second class obese (35–39.9 Kg/m²), and third class obese (≥40).

OSDI

The OSDI sheet was completed by every subject and a normal eye was defined for scores of less than 13.

NITBUT test

The NITBUT test was performed on an OCULUS Keratograph® 4 (OCULUS Inc., Wetziar, Germany) using fluorescein. Each subject was asked to refrain from blinking while the tear film was being observed. The tear break-up time was recorded as the number of seconds that elapsed between the last blink and the appearance of the first dry spot on the tear film. A normal eye was defined as having a tear break-up time of more than 10 sec.

TMH test

The TMH test was performed on an OCULUS Keratograph® 4 (OCULUS Inc., Wetziar, Germany). The inferior TMH images were captured and measured (mm) perpendicular to the lid margin at the central point relative to the pupil center. A normal eye was defined when the lower lid TMH was more than 0.2 mm.
PRT test
Cotton thread (Zone-Quick, Showa Yakuhin Kako Co, Ltd, Tokyo, Japan) containing a pH indicator was used. A 3-mm portion of thread was folded and inserted one-third of the distance from the temporal canthus of the lower eyelid, with the eye in the primary position. After 15 seconds, the thread was removed and the red color portion was measured. A normal eye was defined if the length of the red color portion was more than 10 mm.9

TF test
A small tear sample (1 μL) was collected from the lower meniscus of the eye using a glass capillary tube (10 μL) purchased from Merck (Schnelldorf, Germany). The sample was dried for 10 min at 23 °C and a humidity of less than 40%. An Olympus DP72 digital microscope (Tokyo, Japan) was used to observe and capture the TF images (magnification power of 10×). The TF patterns were graded based on the five-point TF grading scale.34

Statistical analysis
The data were analyzed using version 22 of the SPSS software (IBM, Armonk, NY, USA). A Spearman correlation coefficient (r) was used to assess any association between the data. The correlations were defined as weak (r=0.10–0.29), medium (r=0.30–0.49), or strong (r=0.50–1.00).35 The study group comprised twenty male subjects (31.3 ±5.7 years) with a high BMI [31.8 (5.2) kg/m²]. The control group comprised twenty male subjects (30.2±4.9 years) with a high BMI [31.8 (5.2) kg/m²]. The BMI data were not normally distributed (Kolmogorov-Smirnov test; P<0.05), and the average was represented by the median (interquartile range). The data obtained from the OSDI sheet, and all of the dry eye tests, were normally distributed (Kolmogorov-Smirnov test; P>0.05) and the averages were represented by the mean ± standard deviation (SD).

Results
The average scores for the BMI, OSDI, NITBUT, TMH, PRT, and TF measurements for the study and control groups are shown in Table 1. There were significant (Kolmogorov-Smirnov test; P<0.05) differences in the BMI, NITBUT, and TF scores between the study and control groups. There were some differences in the OSDI, TMH, and PRT scores between the study and control groups, but the differences were not significant (Kolmogorov-Smirnov test; P>0.05). For the study group, the NITBUT and TF tests’ mean scores showed a dry eye condition (8.5±2.8 s and 2.0±1.1, respectively), while these two tests showed a normal eye condition within the control group (14.7±2.8 s and 0.7±0.6, respectively). The NITBUT and TF tests showed eye dryness in 75% (n=15) and 40% (n=8) of the study group subjects, respectively. For the study group, the average score for the OSDI test showed a normal eye condition in a majority of the subjects (n=19). In addition, the TMH and PRT scores showed a normal eye condition (0.21±0.08 and 29.8±5.3 mm, respectively). In fact, the PRT test showed a normal eye condition in every subject within the study group. Figure 1 shows representative TF images for some of the subjects from the study group. Side-by-side boxplots for the OSDI, NITBUT, TMH, PRT, and TF scores within the study and control groups are shown in Figures 2–6.

The correlations (Mann–Whitney test; Pearson correlation coefficient, r) between age, BMI, the OSDI scores and those obtained from the dry eye tests within the study group are recorded in Table 2. The TMH score had strong correlations with the NITBUT (r=0.711; P=0.001) and PRT scores (r=0.566; P=0.009) and strong negative correlations with age (r=–0.503; P=0.024) and the OSDI scores (r=–0.520; P=0.018). The TF score had a strong correlation with age (r=0.579; P=0.007) and strong negative correlations with the scores from the NITBUT (r=–0.525; P=0.018), TMH (r=–0.575; P=0.008), and PRT (r=–0.773; P=0.001) tests. The OSDI score had a strong correlation (r=0.522; P=0.018) with age and a medium negative correlation (r=–0.489; P=0.029) with the PRT score. No correlations were found between BMI and age, or the OSD, NITBUT, TMH, PRT, and TF scores.

The increasing BMI in adults worldwide has become a pandemic, as excessive body weight is prevalent in a number of disorders and diseases. The number of deaths due to obesity is increasing, while both quality and duration of life are decreasing. Therefore, attention must be paid to reversing obesity in order to reduce the risk of life-threatening illnesses. The current study showed that subjects with a high BMI have a significantly lower tear quality compared with those obtained from normal eye subjects, as tested by the NITBUT and TF tests. On the other hand, lower but adequate tear volumes were observed in the study subjects compared with those obtained from the normal eye subjects using the TMH and PRT tests. In addition, the OSDI scores were higher for the study group compared to those recorded for the control group, but both indicated dry eye conditions. Several reports, including a case control and several cross-sectional studies, were conducted to test the link between BMI and dry eye syndrome based on dry eye questionnaires. Those studies showed that there was no association between dry eye symptoms and increased BMI. Dry eye symptoms were more prevalent in men with a low BMI, although a high BMI in women was a preventive factor. In the current study, the TF test was used for the first time to assess the tear film in subjects with a high BMI. The TF patterns reflect the chemical composition of tears and are very sensitive to any disturbance in tear film layers.

Discussion
The increasing BMI in adults worldwide has become a pandemic, as excessive body weight is prevalent in a number of disorders and diseases. The number of deaths due to obesity is increasing, while both quality and duration of life are decreasing. Therefore, attention must be paid to reversing obesity in order to reduce the risk of life-threatening illnesses. The current study showed that subjects with a high BMI have a significantly lower tear quality compared with those obtained from normal eye subjects, as tested by the NITBUT and TF tests. On the other hand, lower but adequate tear volumes were observed in the study subjects compared with those obtained from the normal eye subjects using the TMH and PRT tests. In addition, the OSDI scores were higher for the study group compared to those recorded for the control group, but both indicated dry eye conditions. Several reports, including a case control and several cross-sectional studies, were conducted to test the link between BMI and dry eye syndrome based on dry eye questionnaires. Those studies showed that there was no association between dry eye symptoms and increased BMI. Dry eye symptoms were more prevalent in men with a low BMI, although a high BMI in women was a preventive factor. In the current study, the TF test was used for the first time to assess the tear film in subjects with a high BMI. The TF patterns reflect the chemical composition of tears and are very sensitive to any disturbance in tear film layers.

There was a significant increase in the level of serum triglycerides and total cholesterol in South Indian subjects.
A correlation between an increased incidence of cardiovascular disease and high BMI was reported as possibly being due to an increased atherogenic index. An increased level of lipids in subjects with a high BMI could have led to excessive fat in the visceral adipocytes that release free fatty acids. As a result, triglycerides were synthesized and their levels in the blood increased.

A study conducted on a large population (≥40 years) to test the association between mortality, BMI, and body fat percentage suggested that increased mortality is independently associated with a high body fat percentage and a low BMI. The relationship between BMI and low density lipoproteins has an inverted U shape. The level of low-density lipoproteins increases with BMI within a range of less than 27 kg/m², and becomes steady or decreases above this level. The results were consistent among Spanish and US subjects, including black and white individuals. Metabolic impairment due to metabolic disorders or aging could have been the reasons for these results.

A cross-sectional study conducted on 140 subjects indicated that insulin resistance has strong correlations with BMI, body weight, waist circumference, body fat percentage, and visceral fat level. Protein, carbohydrates, and fat are highly energetic nutrients. Excessive intake of these nutrients could lead to obesity and, therefore, a reduction in fat intake might have several health benefits. Strong associations were found between BMI and protein intake in women and carbohydrate intake in men. BMI is a non-invasive tool and should be used regularly to measure the body’s obesity to avoid the health complications that are associated with being overweight.

**Limitation**

There are some limitations associated with the current study. First, the small sample size; second, the inclusion of male subjects only; third, the environmental factors (eg, high temperature, extreme humidity, and strong sunlight) that the subjects might have experienced immediately before participating in the study were not taken in consideration. A more detailed study is still needed to take into account these limitations and to establish the link between a high BMI, eye dryness, and, in particular, the quality of tears.

**Conclusion**

The acquired data suggest a high BMI has an effect on the quality of tears. The quality of tears seemed to be lower in the subjects with a high BMI compared with the normal subjects. On the other hand, the tear volume
in the subjects with a high BMI was as high and adequate as for the normal eye subjects.
