Abstract: In dermatology, diseases that manifest as blisters or blister-like lesions are common, and some of these features are caused by infectious diseases. Here, we summarize and describe these diseases to increase their clinical awareness and diagnosis.

Keywords: infectious dermatosis, vesicles

Introduction
In dermatology, diseases that manifest as blisters or blister-like lesions are common, and some of these features are caused by infectious diseases. These conditions not only include bacterial and viral infections, but also fungal infections. Some of these diseases can be accurately diagnosed based on typical clinical manifestations and characteristics. However, some are easily misdiagnosed because of the atypical symptoms. In the diagnosis of these diseases, it is necessary to distinguish not only non-infectious skin diseases but also the infectious diseases themselves. Here, we summarize and describe the common infections associated with these diseases to increase their clinical awareness and diagnosis.

Clinical manifestations and characteristics

Erysipelas
Erysipelas is a common soft tissue bacterial infection, and the typical clinical manifestations include redness, swelling, heat, and pain in the local tissue. Some erysipelas infections may exhibit blisters or bullae due to erythema and occasional itching (Figure 1A). The diagnosis of erysipelas can be based on typical clinical manifestations and routine blood tests, and biopsy can be performed if necessary.

Impetigo
Impetigo is a highly contagious bacterial skin infection and is one of the most common skin infections in children, among which 30% of cases are bullous impetigo. Bullous impetigo is caused exclusively by Staphylococcus aureus, and the typical clinical manifestation is large, flaccid bullae that are likely to affect intertriginous areas. The diagnosis of impetigo can be based on typical clinical manifestations, routine blood tests, repeated bacterial culture and drug sensitivity tests.

Serratia marcescens infection
Most Serratia marcescens infections are iatrogenic infections. Skin infections are uncommon, and the appearance of blister-like skin infections is even rarer. We have diagnosed one case of facial Serratia marcescens infection with blisters (Figure 1B).
type of infection involves scratching, “picking” of acne lesions and other traumatic history. The lesions do not involve itching and pain.6–8 This infection is easily misdiagnosed. Etiological tests include bacterial and fungal cultures, and pathological biopsy is extremely important for the diagnosis of this disease.

Leprosy
Leprosy is a teratogenic, disabling disease caused by infection with Mycobacterium leprae. Blister lesions in leprosy are a rare phenomenon and occur clinically in certain types of leprosy and leprosy reactions, thus they are very easy to misdiagnose. Repeated bacteriological examinations, pathological biopsy, and neurological tests are extremely important for diagnosis.9

Chicken pox
Chicken pox can occur in children, young adults, and the elderly, but the disease is most common in children. Typical clinical manifestations of chicken pox include fever and other discomfort, and herpetic lesions on the basis of erythema can be widespread (Figure 1C). Most skin lesions involve mild itching.10 The diagnosis of chicken pox is based on typical clinical manifestations, epidemiological history, and routine haematological examinations. The diagnosis is generally not difficult.

Herpes zoster
Herpes zoster is varicella zoster virus infection that results in reactivation of latent virus. Female sex, age, family history and comorbidities are risk factors for herpes zoster. Classically, a single dermatome is involved, and the lesions usually do not cross the midline. Typical clinical manifestations of herpes zoster include localized erythema and blisters (Figure 1D), and infection is often accompanied by limited pain and itching.11–13 The diagnosis is simple and based on typical clinical manifestations combined with dermoscopic observations and virus detection when necessary.

Herpes simplex
Herpes simplex virus, including HSV-1 and HSV-2 infections, is highly prevalent worldwide. HSV-2 often causes genital herpes and is a leading cause of sexually transmitted infections. A typical clinical manifestation of herpes simplex virus infection is localized rash, including erythema and blisters, often accompanied by a burning sensation and partial pain (Figure 1E). Herpes simplex virus often recurs throughout the lifetime of infected hosts.14,15 The diagnosis is generally simple and based on typical clinical manifestations and virus detection combined with dermoscopic observations.

Hand-foot-mouth disease
Hand-foot-mouth disease (HFMD) is a common viral illness that usually affects infants and children, although it can sometimes affect adults. The main causes of HFMD are coxsackievirus A type 16 and other strains of coxsackievirus.
The virus generally spreads through the respiratory tract. The infection usually involves the hands, feet, mouth and sometimes the genitals and buttocks. Typical clinical manifestations of the infection include erythema and blisters on the hands and feet and vesicles or ulcers in the oral cavity with or without itching and pain (Figure 1F). Different degrees of fever can occur before or when the rash appears.\textsuperscript{16,17} The diagnosis is not difficult and is based on typical clinical manifestations, epidemiological history, and haematological examinations.

**Tinea pedis**

Tinea pedis or foot ringworm is a foot infection caused by dermatophyte fungi, such as *Trichophyton rubrum*, *Trichophyton interdigitale* and *Epidermophyton floccosum*.

The major clinical variants of tinea pedis are the interdigital type, planter moccasin type and vesiculobullous type (Figure 1G).\textsuperscript{18} The diagnosis of tinea pedis relies on typical clinical manifestations, direct smear examination with fungal culture, and staining with Periodic Acid-Schiff stain (PAS) or methenamine silver stain for pathological examination.

**Chromoblastomycosis**

Chromoblastomycosis is one of the most frequent chronic infections caused by melanized fungi, such as *Cladophialaphora carrionii*, *Fonsecaea monophora* and *Fonsecaea pedrosoi*. There are several different clinical manifestations of chromoblastomycosis, including plaque, tumoral, cicatricial, verrucous, pseudo-vacuole, eczematous and mixed types of lesions; the pseudo-vacuole type is very rare (Figure 1H).\textsuperscript{19,20} The correct diagnosis depends on adequate mycological tests including direct examination, culture, molecular biology identification, and histopathology of the lesions.

**Syphilis**

Syphilis is a sexually transmitted disease caused by *Treponema pallidum*. The incidence of syphilis is increasing in China, and it remains a major public health problem. The clinical manifestations of syphilis are often not specific, except for a few specific indicators. Syphilis can be manifested as a variety of other skin diseases; therefore, it is called a “universal simulator”. This also leads to misdiagnosis or missed diagnosis of syphilis.\textsuperscript{21,22} Personal history and blood antibody tests are crucial for the diagnosis of syphilis.

**Mycoplasma infection**

Mycoplasma infection is usually characterized by genitourinary tract inflammation or pneumonia caused by mycoplasma, such as *Ureaplasma urealyticum*, *Mycoplasma genitalium*, *Mycoplasma hominis* and *Mycoplasma pneumoniae*. Mycoplasma-induced skin manifestations, especially blister changes, are relatively rare.\textsuperscript{23} The correct diagnosis may depend on mycoplasma culture, drug sensitivity tests, molecular biology identification, and histopathology of the lesions.

**Possible diagnostic steps**

Infectious dermatoses that can manifest as vesicles include bacteria, viruses, fungi, syphilis and other infections. In many cases, these infections are easily misdiagnosed.

A detailed medical history request is the first step in making a correct diagnosis. Next, a comprehensive physical examination and detailed local examination should be performed. In some cases, it is necessary to use auxiliary tools such as a magnifying glass or a dermascope. Targeted auxiliary blood examinations should include routine blood tests and syphilis serology. Etiological examinations, such as fungal smear, fungal culture and bacterial culture from skin vesicles and/or skin tissue, are necessary.

However, the biopsy of skin lesions is crucial for the final diagnosis.
