Purpose: This study aimed to assess the effects of exercise with dietary restriction on arterial stiffness, central hemodynamics, and cardiac autonomic function in obese adolescents.

Patients and methods: Twenty-one obese adolescents completed a 6-week exercise and dietary program. Body composition and metabolic parameters were measured. Carotid-femoral pulse wave velocity (cfPWV) and brachial-ankle pulse wave velocity (baPWV) were used to assess central and systemic arterial stiffness, respectively. Using applanation tonometry, the analyses of central hemodynamic parameters [central blood pressure, heart rate (HR), augmentation index normalized at 75 bpm (AIx75), and subendocardial viability ratio (SEVR)] were performed. To determine cardiac autonomic function, heart rate variability (HRV) was analyzed by standard deviation of normal R–R intervals (SDNN), root mean square of successive R–R interval differences (RMSSD), percentage of successive R–R intervals that differed by >50 ms (pNN50), total power (TP), low-frequency (LF) and high-frequency (HF) power, and LF/HF ratio.

Results: Following the intervention, obese adolescents had reductions in body mass index, body fat percentage, brachial systolic and diastolic blood pressure, and HR; and they had shown improvements in lipid profiles. There were reductions in both cfPWV and baPWV following the intervention. Moreover, there were reductions in AIx75, aortic systolic and diastolic blood pressure and an augmentation in SEVR after intervention. The intervention increased cardiac autonomic function (determined by increased SDNN, RMSSD, pNN50, HF, and reduced LF/HF). Furthermore, we observed a correlation between increased cardiac autonomic function (SDNN, RMSSD, pNN50 and HF) and increased central hemodynamics, as measured by SEVR and AIx75.

Conclusion: Obese adolescents had increased central hemodynamics and autonomic function with reduced arterial stiffness after exercise and dietary restriction. Moreover, a positive correlation between an enhancement of cardiac autonomic function and an augmentation in central hemodynamics was found after the intervention.

Introduction

The prevalence of obesity among children and adolescents is rapidly increasing in modern societies.1 In 2016, more than 340 million children and adolescents (aged between 5 and 19 years) were reported as being overweight or obese.2 Importantly, childhood and adolescent obesity are associated with an increased risk for...
developing type 2 diabetes mellitus and atherosclerotic cardiovascular disease (CVD) in adulthood. Abnormalities in arterial and cardiac function play a critical role in the increased risk of cardiovascular events in the obese. Obesity-induced atherosclerosis can be characterized by arterial stiffness. Aortic arterial stiffness could be evaluated by carotid-femoral pulse wave velocity (cfPWV), the gold standard for noninvasive assessment of arterial stiffness. In comparison of cfPWV, brachial-ankle PWV (baPWV) is determined partly by systemic arterial stiffness. Greater cfPWV and baPWV have been reported in children and adolescents with obesity.

Using applanation tonometry, the analysis of central hemodynamic parameters [central blood pressure, heart rate (HR), augmentation index (AIx), AIx normalized at 75 bpm (AIx75), and subendocardial viability ratio (SEVR)] is performed, which can be used to assess the central blood pressure, aortic vascular function, cardiac blood supply and endocardial perfusion. Impaired central hemodynamics are independent risk factors for CVD.

Autonomic activity assessment is a potentially useful clinical tool in early identification of children and adolescents at CVD risk. Cardiac autonomic function could be evaluated by heart rate variability (HRV). Furthermore, studies have reported that lower HRV is shown in obese children and adolescents, associated with impaired arterial and cardiac function.

Previous study has indicated that a high calorie intake or sedentary lifestyle dramatically increases the incidence of obesity. Generally, physical activity and diet intervention are beneficial for glucose metabolism, skeletal muscle function, bone stability, psychological well-being, and other organ functions. However, in the current study, we entirely focus on the effects of combined exercise and diet intervention on cardiac and vascular function including PWV, central hemodynamic parameters, and HRV. We hypothesized that obese adolescents would exhibit augmented central hemodynamics and increased autonomic function with reduced arterial stiffness following a 6-week of exercise and diet intervention.

Materials And Methods

Participants
Obese participants aged 10–16 years were recruited from a weight loss camp between July and August 2017. Participants who satisfied the obesity diagnosis criteria [body mass index (BMI) equal to or greater than the 95th percentile for age and sex] were included. All participants were free of metabolic, gastrointestinal, or cardiac disease. None of the participants were taking medications which affected energy expenditure or were losing weight in the past three months whether by diet, taking weight-loss medication or more physical exercise than normal. All participants and their parents signed written informed consent prior to participation. This study was approved by the Ethics Committee of Guangzhou Sport University and conducted in accordance with the Declaration of Helsinki. The trial was registered in ClinicalTrials.gov (NCT03762629). Of the thirty enrolled participants, twenty-three met the criteria for inclusion and were selected for the training program. Twenty-one participants (M/F, 11/10) who completed the program and provided valid measurements at both pre- and post-intervention were included in the analysis (TREND flow diagram, Figure 1).

Exercise And Diet Intervention

The full details of exercise and diet intervention have been published in our previous study. In brief, participants were provided with a calorie-restricted but nutritionally complete diet based on their age. The amount of diet provided met the basal metabolic rate requirement calculated using the Mifflin equation, recommended to determine resting energy expenditure in overweight and obese persons. Dietary plans were made individually according to their own basal metabolic rate. The diet was provided with 60% carbohydrate, 20% protein, and 20% fat, and energy intake was divided as 30% of total daily calories at breakfast, 40% at lunch, and 30% at dinner. The dietitians and nutritionists prepared and supervised all meals. Participants

![Flow diagram of participants through the study.](https://www.dovepress.com/flow-diagram-of-participants-through-the-study)
performed an exercise training program 6 days/week for 6 weeks. The program was primarily comprised of various types of aerobic exercises such as bicycling, walking, running, dancing, and ball games for 5 hrs/day. It was also supplemented by strength training. The endurance exercises involved moderate (70–85% of maximum heart rate) and high intensity (~90% of maximum heart rate) training. Strength training was conducted 2–3 times per week at 40–50% maximal strength for 2–3 sets of 12–15 repetition maximum with 2–3 mins of rest between sets.

**Body Composition And Metabolic Parameters**

Height and weight were determined and BMI was calculated (kg/m²). Body composition was assessed by a body composition analyzer (Inbody 370, Biospace, Seoul, Korea). Fasting blood samples were collected for the assessment of the metabolic parameters [total cholesterol, triglycerides, high-density lipoprotein cholesterol (HDL-c), low-density lipoprotein cholesterol (LDL-c), and glucose].

**Arterial Stiffness And Hemodynamic Measurements**

The details for arterial stiffness and hemodynamic measurements were previously described. In brief, brachial systolic/diastolic blood pressure (SBP/DBP) were measured using a sphygmomanometer (Omron, 705 IT, Omron Health Care, Japan). Arterial stiffness and hemodynamic measurements were performed using a SphygmoCor device (AtCor Medical, Sydney, Australia). An applanation tonometry was used for recording pressure waveforms that include cfPWV, aortic systolic/diastolic blood pressure, HR, AIx, AIx75, and SEVR. SEVR is calculated as area under the curve (AUC) during diastole/AUC during systole. In addition, baPWV and cfPWV were also evaluated with an oscillometric device (boso ABI-system 100; BOSCH & SOHN, Germany).

**Heart Rate Variability (HRV)**

HRV was evaluated in both time and frequency domains using the SphygmoCor system (AtCor Medical, Sydney, Australia). For the time domain, the standard deviation of normal R–R intervals (SDNN), root mean square of successive R–R interval differences (RMSSD), and the percentage of successive R–R intervals that differed by >50 ms (pNN50) were determined. SDNN reflects global HRV, whereas both RMSSD and pNN50 reflect parasympathetic activity. The analysis of the frequency spectrum was performed by applying a Fast Fourier Transform. Total power (TP) in the frequency range (0–0.40 Hz) was divided into two frequency bands: low frequency (LF: 0.04–0.15 Hz, an index of sympathetic system modulation) and high frequency (HF: 0.15–0.40 Hz, an index of parasympathetic system modulation). LF/HF is the ratio of LF to HF.

**Statistical Analysis**

All data analyses were performed using SPSS® Version 16.0 (SPSS Inc., Chicago, IL, USA). A normality test was performed to assess data distribution, and variables that were not distributed normally were analyzed after log transformation. Paired-sample t-tests were used to evaluate the data pre- and post-intervention. Spearman correlation analysis was performed to measure the association between two variables. Data were reported as mean ± SD. Cohen’s d was used to calculate effect sizes on pairwise comparisons, with 0.2, 0.5, and 0.8, representing small, medium, and large effects, respectively. P-value < 0.05 was considered statistically significant.

**Results**

**Effects Of Exercise And Diet Intervention On Anthropometric And Metabolic Parameters**

As shown in Table 1, in response to the exercise and diet intervention, obese participants had significant reductions in body weight (P = 0.000, d = −2.91), BMI (P = 0.000, d = −3.29), body fat mass (P = 0.000, d = −2.99), and body fat percentage (P = 0.000, d = −2.28). Obese subjects also had significantly lower concentrations of serum cholesterol (P = 0.000, d = −1.00) and LDL-c (P = 0.000, d = −1.35). Whereas, no significant changes in levels of fasting blood glucose, triglycerides (P = 0.063, d = −0.48), and HDL-c (P = 0.086, d = 0.44) were found (Table 1).

**Effects Of Exercise And Diet Intervention On PWV**

Using the boso ABI-system 100 device, we detected that baPWV on both left and right sides significantly reduced after intervention (8.70 ± 0.87 m/s vs 7.69 ± 0.93 m/s, P = 0.000, d = −1.45; and 8.47 ± 0.91 m/s vs 7.55 ± 1.08 m/s, P = 0.000, d = −1.35; Table 2). Additionally, we found a reduction in cfPWV using both the boso device (4.98 ± 0.75 m/s vs 4.22 ± 0.88 m/s, P = 0.000, d = −1.22) and SphygmoCor device (5.32 ± 0.85 m/s vs 4.44 ± 0.90 m/s, P = 0.000, d = −1.02; Table 2).

Notes: Values are presented as mean ± SD. Parameters were measured by boso ABI-system 100. Parameters were measured by SphygmoCor device.
Abbreviations: baPWV, brachial-ankle pulse wave velocity; cfPWV, carotid-femoral pulse wave velocity; Aix75, augmentation index standardized to a heart rate of 75/min; SEVR, subendocardial viability ratio; HR, heart rate; bSBP, brachial systolic blood pressure; dSBP, brachial diastolic blood pressure; aSBP, aortic systolic blood pressure; aDBP, aortic diastolic blood pressure.

Effects Of Exercise And Diet Intervention On Central Hemodynamics

Pulse wave reflection was evaluated by using SphygmoCor device. As shown in Table 2, obese adolescents showed significant reductions in Aix75 (P = 0.002, d = -0.80), resting heart rate (P = 0.000, d = -1.47), brachial SBP (P = 0.000, d = -1.40), brachial DBP (P = 0.000, d = -1.58), aortic SBP (P = 0.000, d = -1.76), and aortic DBP (P = 0.000, d = -1.76) following exercise and diet intervention (Table 2). There was a significant augmentation in SEVR after the intervention (P = 0.000, d = 0.92). However, there was no change in augmentation pressure (Table 2).

Effects Of Exercise And Diet Intervention On Cardiac Autonomic Function

When focusing on the HRV indices of obese individuals at the baseline and at the end of 6 weeks of training program (Table 3), we found a significant augmentation in levels of SDNN (65.2 ± 18.98 ms vs 88.3 ± 28.36 ms, P = 0.013, d = 0.73), RMSSD (65.8 ± 27.49 ms vs 100.5 ± 37.68 ms, P = 0.008, d = 0.80), and pNN50 (37.8% ± 17.05% vs 57.8% ± 12.31%, P = 0.008, d = 0.84) using time domain assessment. Moreover, we detected an augmentation in level of LF (P = 0.072, d = 0.54) and a reduction in level of LF/HF (P = 0.047, d = -0.59) using frequency domain analysis. However, there were no changes in TP and LF (Table 3).

Associations Of Changes In HRV Indices With Changes In Central Hemodynamics And Heart Rate After Exercise And Diet Intervention

As shown in Table 4, correlation analysis showed that the change in SEVR was positively correlated with the changes in SDNN (r = 0.518, P = 0.048), RMSSD (r = 0.499, P = 0.058), TP (r = 0.518, P = 0.084), LF (r = 0.520, P = 0.047), and HF (r = 0.459, P = 0.085). Furthermore, the change in Aix75 was negatively correlated with the changes in TP (r = -0.655, P = 0.021) and LF (r = -0.673, P = 0.006). In addition, the change in resting heart rate was negatively correlated with...

Discussion

The results of the present study reported that exercise training and dietary restriction lead to improved anthropometry, lipid metabolism, arterial function, and cardiac autonomic control of participants with obesity. To the best of our knowledge, this is the first study to assess the effects of a combined exercise and dietary intervention on arterial stiffness, central hemodynamics and autonomic function in obese adolescents. The results of this study revealed that obese adolescents had significantly lower central and systemic arterial stiffness, AIX75, HR, brachial and aortic blood pressure, and they also had significantly higher SEVR and HRV after a 6-week exercise training and dietary restriction.

Overweight and obesity are important clinical and public health burdens worldwide. Obesity and cardiovascular disease are inextricably linked. Moreover, childhood and adolescent obesity are predisposed to an increased risk of cardiovascular disease in adulthood. Therefore, the importance and need for early detection and prevention of cardiovascular abnormalities to attenuate potentially progressive cardiovascular damage in obese children and adolescents have been highlighted.

It has been reported that diet and exercise training program improved vascular function in obese children and adolescents. Likewise, our results showed that both cPWV and baPWV were significantly reduced after 6-week intervention in obese adolescents, suggesting that both aortic and systemic arterial stiffness might be improved by changes in lifestyle. Since impaired arterial stiffness is the early diagnosis of atherosclerosis, our results indicate that 6-week exercise and diet intervention are beneficial to improve the arterial stiffness.

SEVR has been considered as a surrogate measure of microvascular myocardial perfusion, and lower values of SEVR indicate poorer perfusion of the subendocardium. Previous studies have shown lower values of SEVR in patients with high cardiovascular risk. However, it has not yet been investigated whether SEVR was significantly enhanced in obese adolescents after the exercise and diet intervention. Our results suggest that a 6-week exercise training and dietary restriction are effective in improving microvascular coronary perfusion in obese adolescents.

HRV has been considered as an index of cardiac autonomic function. Reduced HRV provided an early and sensitive indicator of cardiac impairment. Since the autonomic nervous system is an important determinant of regulating the cardiovascular system and energy expenditure, it is hypothesized to contribute to the pathophysiology of obesity. SDNN was used to represent the global HRV, and we found a significant increase in SDNN in obese adolescents after the exercise and diet intervention. Moreover, we had also observed that both RMSSD and pNN50 values were also enhanced after the intervention. Additionally, frequency domain analysis of HRV showed an increased level of HF and a decreased level of LF/HF after the intervention. These results indicated increased parasympathetic autonomic function.

Consistent with the present study, a previous study has also reported that a weight reduction program induced a change in autonomic activity in children with obesity toward parasympathetic dominance.

Cardiac autonomic nervous system plays a vital role in the regulation of heart rate and vascular tone. Thus, deterioration of autonomic nervous function may contribute to greater arterial stiffness in patients with obesity, type 1 diabetes mellitus, and systemic sclerosis. A novel finding of our study was that an increased parasympathetic autonomic function was correlated with an improvement in central hemodynamics (i.e. increased SEVR and decreased AIX75) after an exercise and diet intervention.
To the best of our knowledge, this is the first study to report a significant association between enhanced autonomic function and improved hemodynamics among obese adolescents undergoing lifestyle modifications of physical exercise and diet intervention. In accordance with our results, a previous study showed that 6 weeks of whole-body vibration training were effective at increasing autonomic function, associated with an augmentation in arterial function in young overweight and obese women. Taken together, these results suggest that the improvement in arterial function would be partially attributed to an increase in autonomic function after exercise and diet intervention.

Previous studies have reported that exercise or dietary modification may increase cardiac autonomic function and reduce arterial stiffness in obese subjects. The beneficial effects of exercise on autonomic function including vagal influence on the heart and arterial baroreflex sensitivity have been reported. The arterial baroreflex plays an important role in modulating heart rate and blood vessel tone to maintain arterial blood pressure. Indeed, an increase in arterial baroreflex sensitivity with an associated reduction in arterial stiffness has been observed following exercise. Furthermore, a significant negative correlation between augmented HRV and decreased resting heart rate was observed in the present study, indicating that the effects of a 6-week program of exercise and dietary restriction on cardiac autonomic modulation and arterial function were partly due to the changes in resting heart rate as well as changes in systolic and diastolic blood pressure. Future studies are needed to examine the mechanisms underlying the association between changes in cardiac autonomic function and arterial function after life modifications.

The present study sought to determine the beneficial effects of a 6-week exercise training with dietary restriction on cardiac and vascular function as well as body composition and lipid metabolism in obese adolescents. Herein, our results revealed that the exercise and diet intervention resulted in significant augmentations in central hemodynamics and autonomic function with a reduction in arterial stiffness. Furthermore, this intervention proved to effectively decrease body weight, BMI, and body fat with improvements in lipid metabolism. In agreement with our findings, previous studies observed reductions in body weight and body fat after 4 or 10 weeks of exercise and diet intervention in obese children and adolescents. Taken together, these results suggest that our program of combined exercise and dietary restriction is an effective intervention in the improvement of body composition as well as metabolic milieu, thereby preventing the development of cardiac and vascular dysfunction in obese adolescents.

There are several limitations to our current study. For example, a control group was lacked during the training program of the intervention. Because the camp program was a traditional residential camp with a specific aim of weight loss. The camp was located in a remote district of the city, and all obese subjects came from all over the country. Therefore, we thought it difficult to recruit an appropriate control group, which had been previously described. In addition, the number of participants was relatively small. Future research on a larger sample size will be conducted.

In conclusion, this study revealed that obese adolescents had improved central hemodynamics and autonomic function with reduced arterial stiffness after a 6-week exercise training and dietary restriction. Furthermore, a positive correlation between an enhancement of cardiac autonomic function and an improvement in central hemodynamics was found after the intervention.
