Central Serous Chorioretinopathy: Pathogenesis and Management

Abstract: Central serous chorioretinopathy (CSC) is a common retina disease and has a relative high recurrence rate, etiology, and pathogenesis of which remains largely ambiguous. The effects on the retina are usually self-limited, although some people are left with permanent vision loss due to progressive and irreversible photoreceptor damage or retinal pigment epithelium atrophy. There have been a number of interventions used in CSC, including, but not limited to, laser treatment, photodynamic therapy (PDT), intravitreal injection of anti-vascular endothelial growth factor agents, and subthreshold lasers. It is not clear whether there is a clinically important benefit to treating acute CSC, which often resolves spontaneously as part of its natural history. Of the interventions studied to date, PDT and micropulse laser treatment appear the most promising.

Keywords: central serous chorioretinopathy, acute central serous chorioretinopathy, chronic central serous chorioretinopathy

Introduction

Central serous chorioretinopathy (CSC) was first identified and described in 1866 by von Graefe, who referred to the disease as “recurrent central retinitis.”

It is a common ocular disease characterized by decompensation of the retinal pigment epithelium (RPE), which results in neurosensory retinal detachment, serous pigment epithelium detachment (PED), and RPE atrophy. It is usually unilateral and predominantly affects young or middle-aged (25 to 50 years) adults, with men being affected more frequently than women.

In its typical presentation, CSC appears as a localized serous detachment of the neurosensory retina involving the region of the macula without subretinal blood or lipid exudates. The margins of the serous detachment are sloping and merge gradually into the normally attached retina of the posterior pole. Occasionally, it is associated with a single or multiple serous PED.

Patients affected by CSC often complain of blurred vision (usually only in one eye), typically perceived as a dark spot or scotoma in the central visual field, with associated image distortion (metamorphopsia). Other common symptoms include micropsia (reduction of the apparent size of objects), mild dichromatopsia (abnormal color perception), and reduced contrast sensitivity. However, CSC may also be asymptomatic.

The visual acuity of people affected by CSC varies widely; Amsler grid testing reveals distortion of the straight lines, which may appear blurred due to a central scotoma. A small relative defect of the afferent pupillary reflex is also occasionally present.
**Disease Course and Prognosis**

The natural course of CSC is often self-limiting, and spontaneous resolution and complete fluid reabsorption often occurs. The visual prognosis is good in 90–95% of cases and visual acuity returns to normal within a few months once the fluid has resolved. The visual distortion often reduces as the eye heals, but in some patients some visual abnormalities may persist even after the fluid has dissipated. Lasting visual symptoms can include localized distortion, reduced color discrimination and decreased night vision (likely caused by a disruption of the retinal microarchitecture), subretinal fibrosis, and scarring or atrophy of the RPE. Poor visual recovery may be associated with advanced age, multiple recurrences, persistent neurosensory retinal detachment, retinal PED, or severe forms of the disease that cause bullous retinal detachment. This variant of CSC is an acute form that may develop spontaneously or following corticosteroid therapy, organ transplantation, hemodialysis, or pregnancy. Bullous retinal detachment is characterized by a serous or serous subretinal exudation, and is thought to be due to an exaggerated breakdown of the permeability of the choriocapillaris, accompanied by single or multiple areas of RPE decompensation, which allows fluid to gain access to the subretinal space. The bullous retinal detachment usually resolves slowly after many weeks or months of blurred vision.

In most cases, CSC is acute (aCSC), with only a single episode of illness occurring in the patient’s lifetime; however, it can be recurrent, and it can become chronic (cCSC). A recurrence of aCSC may occur within 12 months in 30–50% of patients; it may then resolve again spontaneously or continue to cause some vision disturbances. The chronic form, also known as Type II CSC, occurs in approximately 5% of cases.

The definition of cCSC may be somewhat ambiguous because it relies on a temporal criterion (the duration of the serous retinal detachment), and on the presence of extended RPE changes. The duration threshold above which CSC is considered to be chronic varies among different studies, from 3 to 6 months. Diffuse, rather than focalized, abnormality of the RPE is exhibited in cCSC, which produces persistent subretinal fluid. The serous detachment in these cases tends to be shallower, rather than dome shaped, in comparison with aCSC. Persistence of serous retinal detachment in cCSC is associated with progressive RPE decompensation and deterioration of visual acuity.

**Diagnosis**

Diagnosis of CSC usually begins with a standard examination of the retina, which shows central shallow serous retinal detachment; this is confirmed by optical coherence tomography (OCT), fluorescein and/or indocyanine green (ICG) angiography, and optical coherence tomography angiography (OCTA). The visual acuity of the affected eye is usually slightly or moderately reduced due to the decreased focal length caused by the raised retina; this phenomenon makes the eye more hyperopic than before.

Use of an Amsler grid can be helpful to confirm suspected macular edema in less overt cases and may help localize the involved area of the visual field. The morphologic changes that occur in eyes with aCSC are formation of a limited bubble of central serous retinal detachment (Figure 1), RPE detachment, and RPE abnormalities. The outer retinal layers, which include the photoreceptor layer, intermediate line, and inner segment/outer segment (IS-OS) junction, are well-visualized and preserved; occasionally, thickened and hyperreflective tips of detached photoreceptors may be noted. Less frequent findings include focal protrusions of the RPE layer, focal defects in the RPE at the leaking site, minutes fibrinous exudate in the subretinal space, and subretinal precipitates. Lastly, an increased choroidal thickness associated with an increased choroidal vascular component is well detectable with enhanced depth imaging (EDI) OCT, predominantly in aCSC forms. The anatomical resolution of subretinal fluid is concomitant with the normalization of the choroidal thickness.

The chronic form of CSC exhibits diffuse, rather than focalized, abnormality of the RPE, producing persistent subretinal fluid. The serous detachment in these cases tends to be shallower rather than dome shaped in comparison with aCSC. Changes in the RPE include low to effective detached photoreceptor tips. In cCSC, the presence of micro-rips, hypertrophy and atrophy, thickening of the deeper and thinning of the inner choroidal layers, and thinned posterior surfaces of the detached retina with hyperreflective detached photoreceptor tips. In persistent cases, OCT reveals thinning of the outer retinal layers corresponding to the photoreceptor layers, with poor visualization of the IS-OS junction (Figure 2).

Fluorescein and ICG angiography allow observation of the fluid leakage from the choroidal vessels, the fluid
invasion into the subretinal space, and the choroidal blood vessels. Typically, fluorescein angiography reveals one or more fluorescent “pinpoints” indicating fluid leakage. An expanding point of fluorescein leakage with late pooling into a serous detachment (the classic “smokestack pattern”) is visible in 10–15% of cases (Figure 3). If neoretinal detachment persists, it tends to move toward the lower part of the macula leading to depigmentation and secondary decompensation of the inferior RPE, resulting in the clinical appearance of gravitational atrophy of the RPE.25

Indocyanine green angiography reveals focal delays and hyperpermeability of the choroidal circulation, revealing a delayed initial filling of choriocapillaris arteries in the early phase, and dilation of the choriocapillaris veins leaking fluid in the subsequent phases. Use of ICG angiography demonstrates that CSC is likely caused by a primary dysfunction of the choriocapillaris; the fluid build-up seems to occur due to small breaks in the RPE, secondary to choriocapillaris disease.26

OCTA reveals areas of focal hypo- and hyper-perfusion in the choriocapillaris. Though, due to the inability to detect plasma flow, OCTA is not suitable to detect leakage points in CSC with confidence. However, OCTA reliably detects choroidal neovascularization (CNV) in CSC even in the absence of exudative activity and may, therefore,
represent an important supplement in the diagnosis of CSC. Particularly, OCTA imaging revealed that eyes with CNV complicating CSC exhibited significantly lower choroidal vascular component compared to those with CSC without CNV.

Etiology and Pathophysiology
Stress Burden and Personality Traits
As previously discussed, CSC most often affects men who are actively working, often as freelancers, managers, entrepreneurs, or workers burdened by job responsibilities. Psychological stress is considered one of the most important risk factors for developing CSC. In 1986, Yannuzzi observed a strong association between CSC and the “Type-A” personality pattern, or rather, the personality traits of having a competitive drive, a sense of urgency, an aggressive nature, and a hostile temperament. In a later report, impulsiveness, emotional instability, overachievement, and competitiveness were discussed as personality features observed in CSC patients. More recently, the possible association between CSC and the “narcissistic personality” (characterized by an extreme gratification of self) was suggested. During the past two decades, several independent studies have shown that CSC occurs more frequently in men with higher emotional distress a lower frustration tolerance threshold and poor coping strategies for stressful events. The presence of recent psychological stress has been largely demonstrated as one of most important CSC triggers. Resolution of the stressor may be followed by symptomatic improvement in some cases. However, it is still a topic of debate whether stress minimization (e.g., by psychological intervention or using beta-blocker therapy) could prevent recurrences or progression to chronic CSC. Interestingly, Type-A behavior and stress are strongly linked to psychopharmacological medication use and sleeping disturbances, which have also been suggested as possible independent risk factors for CSC. Although the exact mechanisms are still poorly understood, the link between CSC, personality traits, and stress is proposed to be mediated through higher levels of circulating stress hormones, particularly corticosteroids and catecholamine.

Glucocorticoid Use
Many reports have suggested that high blood levels of glucocorticoids (also called glucocorticosteroids, corticosteroids, or steroids), mineralocorticoids, and occasionally testosterone are involved in the pathogenesis of CSC. There is extensive evidence of an important effect of the cortisol hormone on the capillary permeability of the choroid, which may contribute to the underlying pathogenesis of CSC.
Clinical studies on patients with Cushing syndrome, which is characterized by abnormally high levels of cortisol, found concurrent CSC in 5–10% of cases. The increased risk of CSC during pregnancy is also likely driven by increased levels of endogenous corticosteroids, as ocular dysfunction usually appears during the third semester, but generally resolves spontaneously after delivery. Furthermore, abnormal cortisol elevation may explain the association between CSC and erectile dysfunction, which has been recently suggested by the authors of a large case-control study.46

Endogenous cortisol levels are usually higher in patients with CSC47 and the rate of urinary cortisol excretion is increased.48 Exogenous systemic corticosteroids (e.g., cortisol) are commonly used to treat inflammation and allergies, but nasal corticosteroid sprays, eye drops, and topical creams can also trigger CSC, aggravate it, and cause relapses. Above all, inhalant/nasal, oral, and injectable steroids seemed to be significant risk factors.41 Steroid-induced CSC has less male predilection than idiopathic CSC, and frequently has a bilateral presentation. Among solid organ transplant patients receiving long-term corticosteroids, those with renal transplants appear to be at a higher risk, possibly due to underlying renal disease, hypertension, microangiopathy, and previous exposure to hemodialysis, all of which may modify choroidal hemodynamics.

The strong association between steroid use and CSC may be identified by the RPE and choriocapillary receptor reactivity during systemic corticosteroid treatment. Daruich et al49 proposed that excess activation of the mineralocorticoid receptor (MR) in the choroidal endothelial cells, either by aldosterone or glucocorticoids with a high affinity for the MRs, induces upregulation of the vasodilator potassium channel KCa2.3 that modulates smooth muscle relaxation in the choroidal vessels. Systemic treatment with corticosteroids may damage the posterior blood-retinal barrier, altering the permeability of the choriocapillaris and RPE, resulting in focal areas of increased permeability that lead to subretinal fluid accumulation.38 In contrast, mineralocorticoid antagonists reverse the upregulation of KCa2.3 channels in the choroid; this finding supports the use of MR antagonists in CSC treatment.50

Catecholamines

Compared to healthy subjects, CSC patients present with a significant sympathetic overactivation and decreased parasympathetic activity, as observed by blood pressure and heart rate variability.51 This may explain the association between CSC and hypertension, as confirmed by a recent meta-analysis.41 The use of sympathomimetic agents, such as pseudoephedrine, oxymetazoline, ephedra (found in bodybuilding/dietary products), and MMDA (3-methoxy-4,5-methylenedioxyamphetamine, an illicit amphetamine) has been associated with CSC.52,53

The development of CSC has also been noted after the use of phosphodiesterase-5 inhibitors (such as sildenafil), but there is conflicting evidence regarding CSC resolution after treatment discontinuation.54 The autonomic nervous system modulation of the choroidal blood flow may play an important role in CSC pathogenesis, and it is consistent with the damage induced by epinephrine on RPE cells in vitro.

Sleep Disturbances

Shift work and sleep disturbances have recently been suggested as important independent risk factors for CSC.40,41 Cortisol and catecholamine levels are controlled by circadian regulation and can be deregulated in shift workers, thereby contributing to CSC pathophysiology. Other reasons for sleep disturbance were previously identified in CSC patients, including obstructive sleep apnea (OSA). Early reports suggested that early diagnosis and management of OSA could eventually reduce the risk of CSC and preserve ocular function. Although several studies have shown a high prevalence of OSA in CSC patients, there is still insufficient evidence to support OSA screening in patients with CSC.52,55–57

Despite the strong association between sleep disturbance and CSC,41 there have been no studies evaluating melatonin levels and rhythms in CSC patients. Melatonin production is suppressed by light through melanopsin ganglion cell activation during the day, and is typically reduced in shift workers.58 Restoring sleep by reducing stress or by using oral melatonin may, therefore, have potential beneficial effects in patients with CSC.59

Other Factors

Infection with Helicobacter (H.) pylori may be a predisposing factor for CSC. It appears that the presence of these bacteria is correlated with the visual prognosis and severity of the clinical manifestations of the disease. Though the mechanism is still poorly understood, infection with H. pylori allegedly creates an increased susceptibility of the retinal tissue to oxidative stress generated by the inflammation.

Patients suffering from kidney diseases, such as membranoproliferative glomerulonephritis type II, may develop
retinal abnormalities similar to CSC; this is likely caused by choroidal deposits of the same material that originally damaged the glomerular basement membrane in the kidneys.

Genetic risk factors may also play a role in CSC, possibly via the complement system; however, only very rare familial cases have been reported thus far.\textsuperscript{60} Chronic CSC is associated with genetic variants in ARMS2 and CFH, indicating a genetic overlap between CSC and AMD, otherwise alleles in ARMS2 and CFH that determines risk of AMD, may be protective for cCSC.

**Chorioretinal Changes**

Advances in imaging techniques, particularly ICG angiography, OCT and OCTA have led to a better understanding of the pathophysiology of CSC.\textsuperscript{61} Clinical evidence from multimodal imaging, such as choroidal congestion and hyperpermeability with localized areas of choroidal non-perfusion, suggests that choroidal dysfunction is an important underlying cause of RPE dysfunction and subretinal fluid leakage in CSC.\textsuperscript{62} The vascular hyperpermeability and congestion belong to the pachychoroid vascular changes that are believed to underlie the development of focal alterations in the RPE, leading to the formation of PED.\textsuperscript{30,63}

Indocyanine green angiography has demonstrated lobular choroidal ischemia and venous congestion with consequent leakage of fluid from the choriocapillaris. The relative ischemia and increased hydrostatic pressure in the choroidal network create secondary damage in the RPE that leads to the breakdown of the external blood-retinal barrier, causing fluid accumulation in the subretinal space.\textsuperscript{64} The subretinal fluid originates from the choriocapillaris, not the vitreous, thus the photoreceptors receive sufficient nourishment that allows them to survive even during prolonged detachment. For this reason, the patient’s vision is usually totally recovered, even though the disease can last more than a month. However, if the retina is detached for a long period, or if there is a bullous retinal detachment with wide separation of the photoreceptors from the source of oxygen, which is the choriocapillaris, ischemic damage of the photoreceptors may occur. This damage subsequently leads to damage of the RPE via gravitational epitheliopathy. In cCSC, large areas of the RPE decompensate, and central vision deteriorates. The detached retina may also induce release of vascular endothelial growth factor (VEGF) into the subretinal space, thereby delaying spontaneous resolution and, in some cases, lead to a subretinal choroidal neovascularization.\textsuperscript{5,65}

**Therapy**

The prognosis for resolution and visual recovery in patients with aCSC is usually good, thus observation and patient reassurance is considered the best treatment course. Positive converging lenses can be used to improve visual acuity until CSC resolves. Most affected patients recover spontaneously with improvement of visual acuity, reattachment of the sensory retina, and improvement of the other symptoms within 3–4 months.\textsuperscript{6} Conversely, approximately 20–30% of patients will develop one or more recurrences of aCSC, and 5% will develop cCSC. A significant number of these patients develop a limited area of RPE atrophy and depigmentation after resolution of the affected retinal area.

For patients with CSC, it is important to suspend, or replace with an alternative, any current medications containing steroids, including creams, sprays, and eye drops. In patients treated with corticosteroids, only suspension of this therapy will be effective in reducing the bullous retinal detachment.

Faster regression of subretinal exudation may be obtained using laser photoablation applied to close focal sites of RPE leakage, or by photodynamic therapy (PDT) applied to the areas of choroidal vascular hyperpermeability.

However, a recent meta-analysis concerning the therapeutic interventions for aCSC analyzed 25 randomized clinical trials (RCTs) concluded that it is not completely clear whether a clinically important benefit exists to treating aCSC since it often resolves spontaneously.\textsuperscript{66} Nevertheless, treatment should be considered if resorption does not occur within 3–4 months and in cases of aCSC recurrence in eyes that sustained a permanent visual deficit from a previous episode. Treatment is also suggested in bilateral cases of aCSC, in cases with reduced visual acuity in the fellow eye, and in patients that absolutely require prompt restoration of their vision owing to occupational necessity. The majority of ophthalmologists recommend treatment of cCSC.\textsuperscript{10,67–71}

Before the advent of photodynamic therapy, the only treatment option for patients with aCSC was conventional argon laser focal photoablation applied to close focal sites of RPE leakage. It consists of light laser treatment that may be applied directly to the point of angiographic leakage if it is located no more than 400 µm from the fovea. Laser treatment consists of a few spots (3–5 impacts) of small diameter (100 µm), low intensity (100–150 mWatt, so as to achieve a slight whitening of the retina), and short pulse...
duration (100 mSec). The laser treatment induces scar tissue formation on the RPE, while coagulating the cluster of diseased RPE cells. It is plausible that the scar restores the RPE barrier to further subretinal fluid accumulation, allowing the pump function of the surrounding healthy epithelium to return the fluid to the choriocapillaris.

Argon laser treatment of the leakage point of the RPE accelerates visual recovery, even though it does not likely improve the final visual outcome significantly. Only selected cases of aCSC may be treated with conventional argon laser therapy; for many cases the leak is too close to the central macula where photoacoagulation would leave a blind spot, or the leakage is too widespread, and its source is difficult to identify. More recently, navigated laser photoacoagulation (Navilas® System; GmbH, Teltow, Germany) has improved accuracy and comfort for retinal laser photoacoagulation for various retinovascular diseases.

Photodynamic therapy was introduced as an off-label treatment for both aCSC and cCSC approximately 10 years ago and is applied to the areas of choroidal vascular hyperpermeability. PDT utilizes verteporfin (trade name, Visudyne; Novartis AG, Switzerland), a photosensitive dye that accumulates in abnormal blood vessels. When stimulated by a nonthermal red laser light with a wavelength of 689 nm, the presence of oxygen produces many oxygen radicals resulting in local damage to the endothelium and blockage of the abnormal vessels.

After the dye infusion, a laser fluence of 50 J/cm² is directed at the surface of the damaged areas to activate the verteporfin, which triggers a healing mechanism both in the damaged choroidal vessels and RPE. Exploiting the mechanism of causing oxidative damage to the normal vessels of the choriocapillaris, PDT induces the absorption of the subretinal fluid and choroidal vascular remodeling with reduction of choroidal hyperpermeability. The efficacy of this treatment, however, is questionable since PDT is suspected of causing choriocapillaris closure and RPE alterations with subsequent damage to the photoreceptors. In addition, PDT may also stimulate the upregulation of VEGF and choroidal neovascularization. In recent years, various adjustments to the fluence and verteporfin dosage have gained good quality evidence demonstrating a low incidence of adverse effects with this CSC treatment. To reduce PDT toxicity, half-dose PDT, low-dose PDT, and reduced-fluence PDT were introduced. The standard dose of administered verteporfin is 6 mg/m²; a reduced dose of 3 mg/m² (half-dose PDT) has been proposed to treat CSC. A lower dose of 2 mg/m² (¼ dose PDT) was tested, but appeared less effective. Reduced or half-fluence PDT consists of reducing of the laser fluence to 25 J/cm² instead of the standard 50 J/cm². Half-dose and half-fluence PDT have shown little difference in efficacy, and no difference in safety when compared to treatment with the standard/full doses. Nicolò et al performed a retrospective study comparing half-fluence and half-dose PDT, and concluded that half-dose PDT seems to induce a longer duration of effects in patients with cCSC than half-fluence PDT.

Despite its effectiveness, PDT is not practical in most countries owing to economic reasons. Transpupillary thermotherapy (TTT) is a less expensive therapeutic option; it uses a lower temperature than that of conventional laser photoacoagulation, which minimizes permanent retinal and choroidal damage. Recently, this therapy was introduced to accelerate the resolution of CSC. The mechanism by which TTT leads to the repair of RPE damage is not yet completely understood.

Similarly, subthreshold micropulse laser (SML) therapy is a new treatment that controls the thermal elevation induced by conventional continuous wave laser photoacoagulation. Treatment with an SML reduces the thermal elevation by “chopping” a continuous wave beam into a train of repetitive short pulses, which allows the tissue to cool between pulses, thereby reducing thermal buildup. The rise in temperature in the target tissue remains sublethal, but it is able to create a stress response which induces anti-angiogenic effects. Therapy with an SML consists of using a grid to apply micropulsed laser burst to the retinal tissue that cause an approximate 7°C increase in temperature with each 100-microsecond micropulse. This therapy has been applied to the retina using different lasers with different wavelengths (810, 532, and 577 nm), and it seems that thermal elevation of the retina induces the release of a group of molecules known as heat shock proteins (HSPs), which are involved in repairing RPE cells and in reducing the inflammatory cascade. Recently, in comparison to half-dose PDT, the application of 577-nm SML treatment resulted in a slightly greater reduction of the subretinal fluid in patients with chronic CSC.

A similar mechanism of action (sub-lethal thermal effect) has been proposed by Russo et al using an
infrared laser light of 689 nm (the same laser utilized for PDT), and has shown promising clinical results. They evaluated the photothermal effect of near-infrared 689-nm laser treatment (689-LT) versus half-dose verteporfin PDT (hd-PDT) for the treatment of cCSC. Both treatment groups showed significant improvement in BCVA, as well as reductions in central retinal and subfoveal choroidal thickness. Although hd-PDT led to a faster reduction in central retinal thickness, no significant differences were recorded between the groups for any other measured parameter at any time point. The authors thereby concluded that both hd-PDT and 689-LT were effective for treating cCSC, and speculated that the thermal effect stimulating the expression of HSPs may potentially explain the favorable effect of the non-lethal continuous wave 689-LT. Specifically, this near-infrared laser treatment, delivering 95 J/cm² via an intensity application of 805 mW/cm² over 118 seconds, produces a photothermal effect that heats the RPE, potentially eliciting the production of HSPs as a form of TTT.

Additionally, intravitreal injections of anti-VEGF drugs have been used, off-label, for the treatment of aCSC. This group of drugs effectively reduces choroidal hyperpermeability by blocking vascular leakage. Choroidal hyperpermeability is often associated with increased expression of VEGF, although high VEGF levels are not detected in the aqueous humor of CSC patients. Many reports have demonstrated that therapy with anti-VEGF drugs is effective, with good functional short-term outcomes for treatment of acute and chronic CSC. However, during the middle-long term period (six months), low-fluence PDT treatment is more effective than intravitreal anti-VEGF therapy in reducing the subretinal fluid in patients affected by CSC. Semeraro et al compared intravitreal bevacizumab, a recombinant humanized monoclonal antibody that inhibits the biologic activity of VEGF and prevents binding of VEGF to its receptors on the surface of endothelial cells, with low-fluence PDT in patients with cCSC. In a series of 22 patients, no statistically significant difference could be identified between the two treatment groups after 9 months of follow-up; therefore, they concluded that intravitreal bevacizumab may be a valid treatment option for treating cCSC. A recent meta-analysis of 6-month studies showed that patients affected by aCSC who were treated with anti-VEGF drug injections had significantly better BCVA than the observation group at the 1-month follow-up appointment; however, no significant difference was observed for longer follow-up times.

Finally, numerous orally administered drugs have been proposed to treat CSC, including acetazolamide and other diuretics, mineralocorticoid antagonists (spironolactone and eplerenone), 5-alpha reductase inhibitors (finasteride), aspirin, beta-blockers, vitamins, and nonsteroidal anti-inflammatory medications. All these drugs were found to be mostly effective in animal and in vitro studies, but none have been shown to have unequivocal benefits in humans.

Supporting the hypothesis of the role of mineralocorticoids on the pathogenesis of CSC, oral spironolactone and eplerenone have recently been proposed as a treatment option for CSC. Eplerenone acts as a competitive antagonist of the mineralocorticoid receptors that may be active in modulating local permeability in cCSC patients. In three case series treatment with spironolactone and eplerenone resulted in a significant reduction in central macular thickness and submacular fluid in patients with non-resolving cCSC. These drugs seemed to be beneficial and well-tolerated in half of the patients, and a complete resolution of the subretinal fluid 6 months after treatment initiation occurred. In non-randomized studies, treatment with carbonic anhydrase inhibitors (e.g., acetazolamide) has been shown to reduce the duration of CSC, but without significant effect on final visual recovery. Treatment with finasteride, an inhibitor of dihydrotestosterone synthesis, was evaluated in a small series of 5 patients affected by cCSC. Macular thickness and subretinal fluid accumulation diminished during the treatment period, but CSC unfortunately recurred immediately upon planned cessation of the medication.

Conclusion

Central serous chorioretinopathy is an enigmatic disease that is still not completely understood due to its multifactorial etiology, complex pathogenesis, and wide systemic associations. No single treatment has provided overwhelming evidence of efficacy in published RCTs. However, the majority of these studies possess many limitations, specifically a relatively small number of participants and short follow-up periods.

Furthermore, it is not still clear whether there is a clinically beneficial to treat aCSC since it often resolves spontaneously as part of its natural progression. Some studies have suggested that early intervention (within 3 months) results in better visual outcomes, other than a timely treatment did not induce a significant difference in long-term visual acuity. Currently, approximately
79.1% of ophthalmologists tend to observe cases of aCSC, whereas for chronic cases, 66.7% use PDT, with the majority preferring half-fluence PDT. Based on our knowledge regarding CSC pathogenesis, it seems that the best treatment approach for this disease is individualized therapy. Factors that may prompt earlier treatment include the following: recurrent CSC, the patient’s demands, a massive serous detachment, or a history of poor response in the fellow eye to initial observation.

A greater understanding of the pathophysiology of CSC could be provided by future studies using newer imaging techniques, such as optical coherence tomography angiography, which could provide more information as to the reactivity of the choriocapillaris to drugs and other therapies that affect choroidal vessel permeability.

Method of Literature Search
Articles providing data on central serous chorioretinopathy were found by searching PubMed and Google Scholar with the following MESH terms: “central serous chorioretinopathy.” Additional search terms included “central serous retinopathy, central serous choroidopathy.” Case reports were considered only if they provided novel information beyond that already covered in reviews. Publications cited in articles selected by searches were also retrieved. Only articles in English were reviewed, and the full publication was retrieved. No restrictions were applied to the date of publications, which span from 1900 to 2017.

Ethics Statement
The study has been conducted in accordance with the Declaration of Helsinki. This study obtained the approval of the Ethics Committee “Provinciale di Brescia” Approval Number NP2246. The authors confirm that all patients or participants have provided written informed consent for their details to be used in this manuscript.

Acknowledgment
The authors alone are responsible for the content and writing of the paper.
