Background: The oral prednisolone test is widely used to distinguish chronic obstructive pulmonary disease (COPD) patients who might benefit from inhaled steroid treatment. Previous studies used selected patient groups that did not represent the large COPD population in primary care.

Methods: The study included smokers and exsmokers with chronic bronchitis or COPD from primary care, who underwent prednisolone testing (30 mg for 14 days) before randomization in a three-year follow-up randomized controlled trial (COOPT Study). Spirometry was performed before and after the test. Responders and nonresponders were classified according to international criteria. Effectiveness of inhaled fluticasone relative to placebo was compared in terms of health status (Chronic Respiratory Disease Questionnaire), exacerbations, and postbronchodilator forced expiratory volume in one second (FEV₁), using repeated measurement analysis.

Results: Two hundred eighty-six patients recruited from 44 primary care practices were randomized. Nine percent to 16% of the COPD population was classified as responder, depending on the international guideline criteria used. On average, responders did not reach the minimum clinically important difference in health status (0.29 points/year, \( P = 0.05 \)), although a borderline significant effect of inhaled fluticasone was noted. Possible clinically relevant reductions in exacerbation rate (rate ratio 0.67) and FEV₁ decline (39 mL/year) occurred in responders, but did not reach statistical significance.

Conclusions: Oral steroid testing identifies a limited proportion of COPD patients, but does not reveal any clinically relevant benefit from inhaled steroid treatment on health status. No significant effects on exacerbation rate and lung function decline occurred.

Keywords: COPD, primary care, oral steroid testing, prednisolone test

Background

In chronic obstructive pulmonary disease (COPD), many different patient groups are represented. Patients include those with chronic bronchitis to the emphysematous, with overweight or with nutritional depletion, and from irreversible obstruction to having a reversible component besides persistent obstruction. By GOLD definition, and in daily practice, all these groups are termed COPD. In most recent (therapeutic) COPD trials, however, a strong entry selection occurred to ensure population homogeneity, thereby diminishing external validity. From large prospective studies it has become clear that the progressive lung function loss in COPD cannot be altered by inhaled corticosteroid therapy. However, these randomized clinical trials strictly excluded patients with any form of reversibility for methodological reasons. In practice, the diagnostic prednisolone test has been used widely to identify the patients responding...
to oral steroids, thus foreshadowing the presumable efficacy of inhaled corticosteroid therapy. It is disputed what proportion of COPD patients suffer from persistent obstruction with a reversible component. Estimates differ from 10% to 30% depending on clinical setting. It is estimated that 20%–30% of patients with COPD may experience a significant improvement in FEV$_1$ from short-term corticosteroid use.

In case of persistent obstruction with a significant reversible component, a diagnostic prednisolone test can be performed, although the validity of this test is questioned and different cut-off points for ‘response’ are advised according to several international guidelines. Small, short-term studies in selected patient groups have described different regimes of prednisolone testing, and as a result the more or less accepted current form (14 days of 30 mg prednisolone) has been part of the diagnostic work-up of COPD-patients. However, the prednisolone test was never validated prospectively in a primary care population. In severe disease without reversibility it has recently been shown not to be useful by American Thoracic Society (ATS) criteria. As a consequence, the utility and predictive value of responders within the COPD population is vigorously debated. Small, short-term studies in selected patient groups have described different regimes of prednisolone testing, and as a result the more or less accepted current form (14 days of 30 mg prednisolone) has been part of the diagnostic work-up of COPD-patients. As a result, the prednisolone test was never validated prospectively in a primary care population. In severe disease without reversibility it has recently been shown not to be useful by American Thoracic Society (ATS) criteria. As a consequence, the utility and predictive value of responders within the COPD population is vigorously debated.

Methods

The COOPT trial is a double-blind, double-dummy, randomized placebo-controlled clinical trial with a three-year follow-up undertaken in The Netherlands between 1998 and 2004. General practitioner (GP)-diagnosed patients with chronic bronchitis and COPD from 44 general practices participated in the study, when postbronchodilator forced expiratory volume in one second (FEV$_1$) was between 40%–90% predicted, and FEV$_1$/forced vital capacity (FVC) was below 88% (males) or 89% (females) according to former European Respiratory Society (ERS) criteria. A clear history of asthma, allergic rhinitis, or atopic eczema was an exclusion criterion, while reversibility to bronchodilators was not. Outcome measures were health status, as measured with the Chronic Respiratory Disease Questionnaire (CRQ), exacerbation frequency and postbronchodilator FEV$_1$. An exacerbation was defined as an episode with one or more subsequent unscheduled contacts with either a GP or a pulmonologist due to worsening of respiratory symptoms. In this randomized clinical trial a three-leg design was used, with fluticasone propionate and N-acetylcysteine as intervention groups, the third leg as placebo. An independent statistician generated a randomization list based on a block size of three for treatment allocation to balance the three treatment arms by study center. Neither investigators nor patients were aware of the group assignment. In this analysis we compared the fluticasone propionate 500 µg twice daily administered as dry powder inhalation by Diskus inhaler versus placebo legs. A wash-out period of three months preceded the study, allowing any effects of stopping inhaled steroids or N-acetylcysteine to subside. During this wash-out phase, 12% of original study candidates withdrew. In effect, the study group can be described as patients clinically diagnosed as having COPD by their GP, but who did not get worse if inhaled steroids were stopped for three months.

Before randomization took place, all patients underwent the prednisolone test, before and after which lung function measurements were taken. The study was approved by the medical ethics review boards of the hospitals involved. All study subjects gave written informed consent.

The diagnostic prednisolone test is generally defined as FEV$_1$ measurements before and after 14 days of 30 mg prednisolone, but cut-off points for a positive response differ among the various international guidelines. The ATS considered an increase of >12% and 200 mL of baseline FEV$_1$ as a positive response, while the British Thoracic Society (BTS) stated an increase of >15% of baseline FEV$_1$ as a positive response. By contrast, the ERS used to recommend a ≥10% increase of FEV$_1$ predicted in their guidelines, but this recommendation has been left out in the 2004 ERS/ATS Guidelines. Specific criteria for positive response have consequently also been deleted from the British NICE Guidelines and the executive summary of the GOLD Guidelines.

Differences in longitudinal scores on health status, exacerbation frequency, and postbronchodilator FEV$_1$ were tested on an intention to treat basis, by using statistical techniques for repeated measurements. The placebo group has been taken as representing the natural course, relative to the intervention groups. For statistical testing of differences in exacerbation frequency between placebo and intervention groups during the study period we used a correlated time-event model (GENMOD-procedure in SAS; Poisson distribution, compound symmetry correlation structure). To analyze the effects on health status, a longitudinal analysis
was performed on the CRQ-total score, while decline analyses for repeated FEV₁ measurements were used for statistical testing of differences in annual lung function. The regression model for these outcomes accounted for correlation between repeated measurements²⁷ (PROC MIXED in SAS, compound symmetry correlation structure).

Results
The study population is described in Table 1. The number of responders differs from 25 (9%, ERS) to 44 (16%, ATS) depending on guideline used. Responders show a significant higher proportion of females, almost equaling men, in comparison with nonresponders across all guidelines. Age, smoking behavior, pack-years, degree of obstruction, and reversibility to bronchodilator do not differ significantly.

The long-term effectiveness of fluticasone propionate relative to placebo in responders versus nonresponders is shown according to different guideline criteria. Outcome variables are exacerbation rate, health status, and postbronchodilator FEV₁. On average, clinically relevant differences in health status were not reached. Responders according to ERS experienced a borderline significant effect of inhaled fluticasone on health status (0.29 points/year, \(P = 0.05\)), and to a lesser extent in BTS responders (0.26 points/year, \(P = 0.06\)). ATS-responders did not experience any significant benefit from long-term fluticasone use. Possible clinically relevant reductions in exacerbation rate (rate ratio 0.67) and FEV₁ decline (39 mL/year) occurred in BTS responders, but did not reach statistical significance. These effects were similar (rate ratio 0.68, FEV₁ decline 30 mL/year) in ERS-responders, while much smaller in ATS responders (rate ratio 0.78, FEV₁ decline 8 mL/year).

Discussion
To our knowledge, this study for the first time prospectively relates the responses to long-term inhaled corticosteroid therapy to different cut-off points for prednisolone testing in primary care. Between 9% to 16% of the COPD population was classified as a responder depending on criteria used. On average, clinically relevant differences in health status were not reached. Responders according to the former ERS guideline (FEV₁ increase of ≥10% predicted) experienced a borderline significant effect of inhaled fluticasone on health status (0.29 points/year, \(P = 0.05\)) during three years of treatment. A similar, but not significant effect on health status (0.26 points/year, \(P = 0.06\)) was seen using the former BTS criteria, while ATS responders showed less effect (0.20 points/year). Possible clinically relevant reductions in exacerbation rate (rate ratio 0.67) and FEV₁ decline (39 mL/year) occurred in responders according to BTS, but did not reach statistical significance. Similar results were seen in the ERS group (rate ratio 0.68 and +30 mL, respectively) but were less similar when the ATS criteria was applied (rate ratio 0.77 and +8 mL, respectively).

Interestingly, the only other long-term prospective study²¹ that assessed prednisolone testing on these outcomes, but not in a primary care population, concluded on the basis of using ATS criteria that there was ‘no relationship between the

short term response to prednisolone and the rate of decline in
FEV₁ or health status’. In fact, our results are in line with that
widely cited study, since we only found any possibly mean-
ingful results using the ERS and BTS criteria. In addition, the
Isolde researchers looked at the so-called Callahan criteria
(FEV₁, increase of 20% of baseline), which were derived from a
meta-analysis looking at oral corticosteroid therapy, not
prednisolone testing. In fact, this cut-off indeed also showed a
significant effect, but this was deemed by the Isolde research-
ers to be the result of confounding. Thus, the criteria used
appears to matter and we cannot recommend the use of the
former ATS criteria when performing prednisolone trials,
based on our results and on those of the Isolde researchers.

In our study, the proportion of primary care COPD patients
meaningfully labeled as responder ranges from 9% (ERS)
to 12% (BTS), which is considerably lower than expected.
We therefore fear that our study was underpowered, since
estimates in literature ranged from 20%–30% responders.
However, it is also possible that we underestimated the
number of potential responders in the population, since
for ethical reasons our study design provided a wash-out
period to exclude all patients that experienced more than
two exacerbations when inhaled steroids were taken in the
three months preceding entry to the study. In our population,
this means that steroid-dependent patients were not allowed
to enter the study.

Contrary to the Isolde researchers, we found a significant
gender difference in prednisolone responsiveness across
all criteria groups. Women appear particularly prone to
COPD when exposed to similar amounts of tobacco and
interestingly, the proportion of female COPD patients
responding to prednisolone was consistently higher than among
nonresponders at baseline. No other significant differences
were seen between responders and nonresponders in terms of
age, lung function, current smoking, or pack-years of smoking.
This apparent gender difference in prednisolone response
therefore deserves further study, since earlier studies probably
did not include sufficient numbers of females with COPD,
whose prevalence has been seen to rise only in recent years.

In this study, a clear history of asthma, allergic rhinitis or
atopic eczema was an exclusion criterion, while reversibility
to bronchodilators was not. However, we found no relation-
ship between prednisolone response and bronchodilator
reversibility, which was very similar across all criteria groups
(Table 1). We consider it highly relevant to clinical practice
that reversibility to bronchodilators apparently does not
match to prednisolone responsibility, since these terms
are sometimes interchangingly used as parameters of the
same phenomenon. These study data indeed suggest that the
response to oral steroids may describe a different underlying
inflammatory process than the response to bronchodilation,
which is of a fundamentally different origin.

Our results suggest a borderline significant effect
on health status in ERS responders, but is it clinically
meaningful? The minimum clinical difference on the CRQ
is 0.5 points, which is clearly higher than the 0.29 points
reached on average in our study, which renders this result
marginal. However, the rate ratio for exacerbations (32% less
than placebo) and even the FEV₁ decline (30 mL/year less
than placebo) point in the same direction in both the ERS

and BTS groups (33% less exacerbations and 39 mL/year less FEV₁ decline, respectively), which may indicate possible clinical relevance. The systematical difference in effects on all three outcomes compared to the nonresponders (and indeed the total group of COPD patients) suggests that this rather small group of responders to prednisolone could be a limited subgroup in primary care, which would need different medical treatment. Since the number of responders (using the ERS or BTS criteria) now can be expected to be around 10% in a primary care population like ours, we think these results would probably need replication in a larger primary care study. This small but possibly relevant proportion is identical to the 10% that was found in the earlier meta-analysis on the benefits of oral corticosteroid therapy for COPD patients. As has been stated before, it is important to keep an open mind about the possibility that there may be responder and nonresponder subgroups and to continue to seek ways to identify and characterize them, especially in primary care where heterogeneity is common.

Conclusions
Oral steroid testing distinguishes a limited proportion of COPD patients, but does not reveal clinically relevant benefit from inhaled steroid treatment on health status. No significant effects on exacerbation rate and lung function decline occurred.

Acknowledgments
The authors would like to thank all participating patients, general practices, and colleagues for their efforts, which enabled the completion of this study. This study was registred at the Dutch Council of Health Insurances (Trial registration number, 98-46140). Funding was provided by the Dutch Council for Health Insurances with complementary funding by the Netherlands Asthma Foundation. Medication was provided by GlaxoSmithKline, Zambon, and Boehringer-Ingelheim. The authors report no conflicts of interest in this work.
