Background: Dermatophytosis represents one of the common infectious diseases worldwide and it is a major public health problem around the globe. The disease causes considerable morbidity and still continues to increase especially in developing countries.

Objective: This study was undertaken to determine the prevalence of dermatophytes and the spectrum of fungal agents in patients attending Rank Higher Specialized Dermatology Clinic.

Methods: A cross-sectional study has been conducted, in which 318 samples from 318 suspected patients were collected. Samples include hair, nail, and skin. A portion of each sample was examined microscopically and the remaining portion of each sample was cultured onto plates of Sabouraud’s dextrose agar containing chloramphenicol with and without cycloheximide. Isolates were identified by studying the macroscopic and microscopic characteristics of the colonies.

Results: Tinea capitis was the predominant clinical manifestation accounting for 53.4% of the cases. Patients with age group 1–14 years were more affected. Of 318 samples, fungi were detected in 133 (54.4%) by direct wet mount while 148/315 (46.5%) of them were culture positive. From these 72/148 (46.8%) were dermatophytes. T. tonsurans was the most common pathogen in tinea capitis, whereas T. mentagrophytes was the most common pathogen in tinea corporis. Among dermatophyte isolates, T. tonsurans 29/72 (40.2%) was the most common cause of infection. Among non-dermatophyte molds, Cladosporium spp. 21/63 (33.3%) was predominant isolate followed by Neoscytalidium dimidatum 11/63 (17.4%) and Alternaria spp. 9/63 (14.2%), respectively. Yeasts also account for 13 (8.7%) of the total suspects of dermatophytosis.

Conclusion: In this study, the prevalence of dermatophytes was higher in tinea capitis 46/72 (63.8%) and T. tonsurans 29/72 (40%) was the dominant-isolated dermatophyte. Recovery of a large number of dermatophytes and non-dermatophyte fungi in our study showed that non-dermatophyte fungi are emerging as important causes of dermatophytosis warranting further intensive epidemiological studies that have public health significance are needed.

Keywords: dermatophytes, non-dermatophytes, dermatophytosis, fungi, infection

Background
Dermatophytosis represents one of the common infectious diseases worldwide and causes chronic morbidity, especially in developing countries.1 The condition is caused by dermatophytes, which are fungi that require keratin for growth. An increase in the incidence of dermatophytosis has been noted worldwide, especially in developing countries.2,3 Tinea capitis, an infection of the scalp, is one of the most common dermatophytosis and represents a major public health issue among children mainly in African and Caribbean regions.3,4
Dermatophytosis is a common public health problem and minor condition in Africa including Ethiopia. The distribution of these fungi varies considerably, depending on epidemiological factors and geographical area (4, 5, 6). T. rubrum, T. interdigitale, M. canis, M. gypseum, and E. floccosum are distributed worldwide. Other species have a partial geographic restriction, such as T. schoenleinii, T. violaceum and T. tonsurans are distributed in Eurasia and Africa; T. soudanense, distributed in Africa.\(^7\)\(^8\)

Geographic location, health care, immigration, climate (temperature, humidity, wind, etc.), overcrowding, environmental hygiene culture, awareness to dermatophytes, age of individuals, hygiene and socioeconomic conditions have been described as major factors for these variations of dermatophyte epidemiology.\(^9\)\(^-\)\(^12\) Children’s between the ages of 4 and 16 years are more at risk due to more contact to different sources and inadequate amount of fungi-inhibiting fatty acids synthesized predisposed them to dermatophytic infections.\(^13\)\(^-\)\(^14\)

Nowadays, there are about 52 known species in seven genera of dermatophytes.\(^15\) Of these species, about 20 species belong to the three most recognized and prevalent worldwide genera; Epidermophyton (1 species), Microsporum (3 species) and Trichophyton (16 species) and these genera’s are presently known to infect humans.\(^12\)\(^-\)\(^15\)\(^-\)\(^17\)

Ethiopia is a developing nation located in the tropical region with a wet humid climate which makes it to fall into regions with a high prevalence of dermatophytosis.\(^14\)\(^,\)\(^16\) However, the distribution of pathogenic species and the dominating anatomical sites of infection vary with geographical location and change over time. The aim of this study was to determine the epidemiological and etiological fungal agents causing dermatophytosis regardless of the site of infection and age.

**Methods**

**Study Areas and Population**

A prospective cross-sectional institution-based study was carried out from January 2019 to June 2019 among dermatophytosis-suspected patients who visit Rank higher specialized dermatology clinic, Addis Ababa, Ethiopia.

**Sample Size Determination and Sampling Technique**

The required sample size of the study was determined using the formula for single population proportion and 318 study participants were included. A total of 318 clinical samples from 318 suspected patients (one sample from every patient based on their clinical manifestation) were collected from patients visiting the Dermatology clinic during the study period were included in the study.

**Biological Sample Collection**

Before collecting the sample, the infected area was cleaned with 70% (v/v) ethanol. Scraping samples from skin, nail, and finger-based on their clinical manifestation were collected aseptically using sterile blades and transferred into sterile plastic Petri-dishes. In tinea capitis suspects, dull broken hairs from the margin of the scalp lesion with forceps were sampled and transferred to sterile folded papers and transferred into sterile Petri dishes.

**Culture and Microscopic Examination**

A portion of each sample was mounted in a drop of 10% (w/v) potassium hydroxide on a clean microscopic slide. After 5 min, the mount preparation was examined under low (×10) and high (×40) power magnification for the presence of any fungal elements. The clinical sample was cultured onto Sabouraud’s dextrose agar plates containing chloramphenicol with and without cycloheximide (Oxoid, Basingstoke, England) prepared according to the instruction of the manufacturer. All inoculated plates were then incubated at an inverted position at 25–30°C for 4–6 weeks. Culture plates containing the Sabouraud’s dextrose agar were examined twice a week for any fungal growth. In the absence of growth during the 6th week, the results were considered negative. Those suspected colonies for dermatophytes were sub-cultured into potato dextrose agar (Oxoid, Basingstoke, UK) for the production of spores. Cultures of dermatophytes were identified by examining macroscopic and microscopic characteristics of their colony on Sabouraud’s dextrose agar. For the macroscopic identification, the rate of growth, texture, topography, and pigmentation of the reverse and front side of the culture were employed. Mold isolates were identified microscopically by placing pieces of the colony from Sabouraud’s dextrose agar and Potato Dextrose agar plates in to clean microscopic slide and stained using lactophenol cotton blue stain. Each preparation was observed microscopically after placing a coverslip. In addition, the urease test was also used in differentiating between some members of *Trichophyton species*. For the identification of yeasts, conventional routine diagnostic methods, and chromogenic medium, CHROMagar Candida (bioMérieux, France) as per the instruction of the manufacturer were used. All ethical considerations were dully addressed and the study was conducted after the approval of the ethical review committee of Medical
Laboratory science, college of health sciences, Addis Ababa University. Written consent was obtained from study subjects after ethical approval.

Statistical Analysis
Data were collected, double entered, cleaned and analyzed using SPSS version 20 software according to the study objectives. Frequency and percentage were used for investigation of the outcome.

Results
From the total of 318 clinical samples from suspected patients, 193 were females. The age of the study subjects ranged from 1 to 88 years with a mean age of 16 years. Among these, fungi were detected in 133/318 (41.8%) samples using potassium hydroxide wet mount while, 148 (46.5%) were culture positive (Table 1).

Tinea capitis was the dominant clinical manifestation 170/318 (53.4%) and this was more present in females than males 98/170 (74.5%). This was followed by tinea corporis and tinea unguium accounting for 30.50% and 16% of the cases, respectively (Table 1).

Dermatophytic infection rate was high in the age group of 1–14 years. Clinical manifestation in relation to age group was highest with age group <14, 144/318 (45.2%) followed by age group 25–44 years accounting for 96/318 (30.1%). Among 170 tinea capitis, 115/170 (67.6%) was found to be in patients age <14 years old and tinea corporis, the second-most clinical manifestation 97/318 (30.6%) was highest in patients of age group 25–44 years, 93/72 (44.3%). Tinea unguium was common in patients of age group 25–44 years (Table 3).

Tinea capitis was the predominant clinical manifestation accounting for 53.4% of the cases; of which 98 (57.6%) were females and 72 (42.4%) males. This was followed by tinea corporis and tinea capitis accounting for 30.5% and 16% of the cases, respectively (Table 4). According to species frequency in different areas of involvement, T. tonsurans was the most common pathogen in tinea capitis, whereas T. mentagrophytes was the most common pathogen in tinea corporis (Table 4).

A total of 148/318 (46.5%) fungi were cultured from skin, hair and nail samples. Of these, 72/148 (48.6%) were dermatophytes, 63/148 (42.56%) non-dermatophyte molds and (13/148) 8.7% were yeasts. T. tonsurans 29/72 (40.2%) was the predominant dermatophyte followed by T. mentagrophytes 13/72 (18%) and M. audouini 13/72 (18%) whereas Trichophyton schoenleini 72/170 (41.8%) was the least common (Figure 1).

Among non-dermatophyte molds Cladosporium spp. 21/63 (33.3%) was the predominant isolate followed by Neoscytalidium dimidiatum 11/63 (17.4%) and Alternaria spp. 9/63 (14.2%), respectively. Cladosporium spp., Neoscytalidium dimidiatum, Alternaria spp. were the dominant isolates in tinea corporis, tinea unguium, tinea capitis, respectively. Yeasts were the least common isolates accounting 13 (8.7%) of the total suspects of dermatophytosis (Figure 2).

Discussion
Dermatophytosis is a major and common public health challenge in many parts of Africa. Accurate diagnosis based on the clinical symptoms alone is nearly impossible. Currently, the diagnosis of dermatophytosis in developing countries is confirmed by clinical examination and using microscopic and culture methods as conventional diagnostic tools. In the present study, direct microscropy positivity rate is 133/318 (41.8%) and culture positivity rate is 148/318 (46.5%) (Table 1). Earlier studies

conducted in Addis Ababa, Ethiopia found that 42.6%, 74% and 85.2% culture-positive for dermatophytes.\textsuperscript{4,6,14} This occurrence is due to that; Ethiopia is a tropical country with wet humid climate, large population size, and low socioeconomic status and correlations between dermatological infections and low socioeconomic conditions, geographical locations, climate, overcrowding, health care, and hygiene have been demonstrated by many researchers.\textsuperscript{14,20,21} Tinea capitis was the most common clinical manifestations followed by tinea unguium and tinea corporis and this is in line with studies conducted in Addis Ababa, Ethiopia (4, 6, 14, 22). And this is due to low socioeconomic status, overcrowding and poor personal hygiene. T. tonsurans (56.5%), M. audouinii

(17.3%), *T. verrucosum* (8.4%), and *T. mentagrophytes* (6.3%) were found the predominant causal agents of tinea capitis in this study. These findings seem to agree with the findings made by Tekleberhan et al., Raccurt et al., Enwean et al., and Al Shimma et al. The most susceptible persons to tinea capitis were patients 1–14 years old (67.6%) and this is due to the inadequacy of natural protective fatty acids synthesized in their scalp among prepubescent children. Earlier, several authors have supported this finding. Many cases occurring in adults is involved with hormonal disorders resulting in carryover of tinea capitis from childhood or in patients with severe immune depression due to HIV/AIDS, leukemia, lymphoma, or treatment with immunosuppressant drugs.

Tinea corporis (33/318) (10.8%) was the second-most common infection with a significant incidence among age groups of 25–44. The site of infection was mostly restricted to face and neck. *T. mentagrophytes, T. rubrum,* and *M. audouinii* were the main causative agents and this is in line with a study conducted in Ethiopia. Tinea unguium 51/318 (16%) was observed mainly at the age of 14 years old 115/170 (67.6%) and this time appears as a contaminant. But some studies showed that they are associated as an opportunistic infection in subcutaneous and disseminated form, especially among immunodepressed individuals. *Neoscytalidium dimidiatum* was isolated from skin and nail scrapings predominantly of toenails. *Neoscytalidium dimidiatum* and *Scytalidium hyalinum* are common causative agents of human superficial infections in different parts of the world, especially in tropical and subtropical regions. Similarly, yeasts were isolated from 13/148 (8.78%) cases with *C. albicans* as a major isolate accounting 5/13 (38.4%) of the total yeast isolated and this study was similar to a study conducted in Saudi Arabia. Non-dermatophyte fungi were isolated as a cause of dermatophytosis in many studies.

**Conclusion**

This study showed that the prevalence of dermatophytosis was 46.5% but in developed countries, it was less than 5% which indicates that dermatophytosis is still a common problem in developing countries. Tinea capitis was identified as the most prevalent clinical presentation and children’s are the most vulnerable group. This study found that *T. tonsurans* was the most common etiologic agent followed by *M. audouinii* and *T. mentagrophytes*. We recommend further research on the possible risk factors and spectrum for dermatophytes and non-dermatophyte molds in large clinical setting and the community.

**Data Sharing Statement**

The data sets used or analyzed during the current study are available from the corresponding author on reasonable request.

**Ethics and Consent Statement**

Ethical clearance for this study was provided from Medical Laboratory science, college of health sciences, Addis Ababa University ethical review committee and the study was conducted in accordance with the declaration of Helsinki. Written informed consents were obtained from participants after ethical approval and we also explained to them the purpose of the study verbally. Assent form was completed and signed by family members and/or adult guardian for participants under the age of 18 years.

**Acknowledgments**

We thank Dr. Zemenu Tamir, Daniel Kahase for proofreading and revision of the manuscript. We are also thankful for the help of Dr. Adane Bitew and Addis Ababa University, Medical
Laboratory Science department staffs for helping with the laboratory activities. We also thank the study participants.
