Introduction: Psoas hematoma is an uncommon complication following spinal surgeries. It has been reported in both extreme lateral interbody fusion (XLIF) and posterior spinal fusion with instrumentation. Minimally invasive techniques are gaining popularity in recent years due to the appealing advantages of reduced operative time, blood loss, hospital stay, and faster recovery.

Case Presentation: We are presenting a case of a 77-year-old male with chronic low back pain, diagnosed to have multilevel degenerative disc disease with central and foraminal disc protrusion at L2-L3, L3-L4, L4-L5 with secondary spinal stenosis, underwent XLIF at L3-L4, L4-L5 and then 2nd stage with posterior L3-L5 fusion with pedicle screws. On the fourth day post-operatively, the patient had flank pain and dropping hemoglobin with femoral nerve palsy symptoms, a CT scan revealed a large psoas hematoma. Conservative management was decided on; a follow-up CT scan and examination showed complete resolution of the hematoma and femoral nerve recovery.

Discussion: The approach to iliopsoas hematoma post spinal surgeries remains controversial. Iliopsoas hematoma should be suspected in any patients post spinal surgeries even with delayed presentations. The decision to proceed with either surgical intervention or conservative management depends on multiple factors, including patient hemodynamic status, progression of collection and femoral nerve palsy.

Conclusion: The exact cause of iliopsoas hematoma post different spinal surgery approaches remains vague. In our opinion, other causes including pre- and post-operative anticoagulants should be investigated. Rushing to drain iliopsoas hematomas in case of femoral nerve palsy might not be the ideal option. Instead, monitoring patient responses to resuscitation and taking a watch and wait approach for femoral nerve palsy might be the proper approach.

Keywords: psoas hematoma, extreme lateral interbody fusion; XLIF, posterior spinal fusion, femoral nerve palsy

Introduction

Intramuscular psoas Hematoma is an uncommon condition and it has multiple causes including trauma, use of anticoagulation, iatrogenic injury during lumbar procedure and bleeding disorders.¹ Extreme Lateral Interbody Fusion (XLIF) is a far lateral approach; allowing access to the anterior aspect of the spine from the level of T6 to the level of L5.² This minimally invasive surgery is retroperitoneal

using a muscle splitting approach through the psoas muscle.^{2,3} Using this approach allows the surgeon to do a complete discectomy, distraction, and interbody fusion.³ Unlike anterior and posterior approaches to the spine, lateral approach is associated with less complications and morbidity rates.⁴ In addition, it has many advantages including reduced operative time, reduced blood loss, minimal wounds, shorter hospital stay and faster recovery time post-operatively.⁴ This can achieve reduction in the peri-operative morbidity through less invasive techniques and shorter hospitalization in order to address different spinal pathologies.⁵ Spinal canal stenosis is a pathological condition and it can be central, lateral recess or foraminal. Central and lateral stenosis can be decompressed using XLIF.⁶ Patient selection has very high importance in achieving satisfactory clinical outcomes to the patient and surgeon. For example, in anterior or posterior lumbar interbody fusion approaches (ALIF, PLIF), the need for resection of important structures like anterior longitudinal ligament, posterior longitudinal ligament, facet joints, pars interarticularis and sometimes they are healthy structures, consequently need stabilization by instrumentation. Alternatively, XLIF respecting these structures and keeping them in tension in order to provide better stability and avoid instrumenting the spinal segments.⁷ However, combining XLIF and PLIF can be of great importance in providing extra stability in case of adult degenerative scoliosis.⁸ We report a case of large intramuscular iliopsoas hematoma post XLIF and PLIF for degenerative lumbar scoliosis, presenting 4 days post-operatively with femoral nerve palsy. Treatment was conservative management with full recovery at 4 month follow-up. Written informed consent was obtained from the patient for publishing this paper.

Case Presentation

The patient is a 77-year-old male, with known cases of Rheumatoid Arthritis, Bronchial Asthma, and Chronic Obstructive Pulmonary disease. He presented to our clinic with a history of low back pain radiating to left lower extremity for several years. The pain was gradually increasing in severity, aggravated by walking up hill and relieved partially by pain medications associated with neurological claudications. There was no history of bowel bladder dysfunction or other cauda equina symptoms. The main complaint was pain that affected his daily living activities. Back examination revealed no obvious deformity with scar in the lumbar

area from previous surgery. No tenderness or hotness was appreciated. Flexion of 70 degree and extension of 20 degrees was achievable. The Adams forward bending test negative. A straight leg rise test was positive at 40 degrees hip flexion. Distal neurovascular exam was normal apart from decreased power on the left lower limb (4/5). The patient presented 2 years before the current presentation with a similar history of pain. An MRI at that time showed L4-L5 broad based central and right paracentral disc herniation with severe critical canal stenosis with foraminal narrowing related to disc height loss and multilevel degenerative disc disease. For which he underwent L4-L5 lumbar laminectomy and decompression. Post-operative period was unremarkable and patient discharged home. Pre-operative X-rays during this presentation showing significant instability and degenerative scoliosis is demonstrated in (Figure 1). MRI entire spine showed multilevel degenerative disc disease with L1-L2 and L2-L3 dorsal complex of disc protrusion and osteophytes, L3-L4 interval progression with secondary spinal stenosis, L4-L5 reduced spinal stenosis compared to previous images (Figure 2). Underwent XLIF technique at L3-L4, L4-L5 and then 2nd stage with posterior L3-L5 fusion with pedicle screws with standard surgical steps without any complications (Figure 3). Four days post-operatively; the patient demonstrated lateral flank bruises and discoloration with dropping hemoglobin from 12 to 8.4 g/L during follow-up complete blood count and left groin pain and numbness. An abdominal CT scan was obtained, showing large left-sided retroperitoneal hematoma measuring about 8.3 × 8.5 × 17 cm in AP, transverse, and craniocaudal diameter respectively, inseparable from the left iliopsoas muscle (Figure 4). Moreover, post-operatively the patient was on heparin 5,000 units subcutaneously twice a day and his coagulation profile pre-operatively was normal, post-operatively was slightly disturbed with INR 1.3, PT 15.9 and PTT 38.5. Patient was not known to have any coagulopathy but he was on aspirin preoperatively, which was supposedly stopped 7 days before surgery, but the patient did not. General surgery and medical teams were involved, transfusion of 4 units of Packed Red Blood Cells (PRBC), 6 units of Fresh Frozen Plasma (FFP) and 2 units of platelets done for the patient. Patient was stable afterwards, and was on close observation. Conservative management was undertaken, with follow-up CT scan showing no progression. Patient was discharged few days later in stable condition with symptoms and signs of femoral nerve palsy; follow-up CT scans revealed resolution of the

hematoma (Figure 4). Outpatient follow-up 4 months later revealed complete resolution of the palsy.

Discussion

XLIF is a minimally invasive technique, gaining popularity in recent years. Traditionally, interbody fusion is achieved through open surgical approach either through ALIF, PLIF or transforaminal interbody fusion (TLIF).^{9–12} Ozgur et al (2006) described XLIF thoroughly. With many advantages over other approaches including decreased risk of injury to great vessels, less operative time, less blood loss and eliminates the need for general surgery.³

Psoas hematoma presentation can be equivocal, leading to difficult and delayed diagnosis due to its retrofascial location.¹³ As in our case, 4 days later the patient started to have ecchymosis over the flank area with dropping

hemoglobin post-operatively from 12 to 10 then 84 g/L and hypotension with femoral nerve palsy. Despite that, there was no any active bleeding encountered during surgery and no immediate post-operative findings suggesting retroperitoneal hematoma. Varieties of symptoms were described for psoas hematoma including hip pain with the hip flexion position to decrease irritation to the psoas. Others may have radicular pain in the thigh due to compression of lumbar nerve roots,¹⁴ or femoral nerve palsy leading to weakness in hip flexion knee extension.^{15,16} Moreover, a fever should raise the suspicion of infection, including hematoma with superimposed infection with late presentation. However, it has been reported that hematoma may cause fever by the release of endogenous pyrogen or interleukin-1.¹⁷

A variety of etiologies for iliopsoas hematoma is described in the literature, including trauma, iatrogenic injury, use of anticoagulants, and coagulation disorders such as hemophilia and disseminated intravascular coagulopathy.^{14,18–22} However, our patient had a normal coagulation profile and no active bleeding during surgery. But he was on prophylactic heparin 5,000 units twice daily post-operatively and was on aspirin pre-operatively. Joshua et al reviewed 3,950 cases of minimally invasive lateral lumbar retroperitoneal transpsoas interbody fusion, found 7 cases of iliopsoas hematoma (0.18%), 3 of which required surgical evacuation without improvement in neurological outcomes post-surgery. They documented only 1 case of confirmed segmental artery injury, while only suspected it in the rest of the patients. Moreover, only 2 patients were receiving anti-platelets prior to surgery.^{16,20} In addition, a retrospective study included 2,998 patients who underwent minimally invasive lateral interbody fusion reported a total of 5 cases of retroperitoneal hematoma. Three of which were identified to be due to segmental vessel injury. One patient was managed conservatively, while the others required intervention.²³ Furthermore, others discussed the possibility of intertransverse plane injury in the development of iliopsoas hematoma. As described by Chung et al in a 13-year-old patient with adolescent idiopathic scoliosis required posterior spinal fusion and instrumentation from T11 to L4. During their dissection on the posterolateral gutter on the concave side of lumbar spine, fascia was violated at L2 level during exposure of the intertransverse plane. But no active bleeding was encountered and no neurological deficit was found post-operatively. They thought that it might be the reason behind iliopsoas hematoma.^{24,25} In general, the rate of iliopsoas hematoma

post minimally invasive spine surgery is low.^{26,27} In a review article discussing the complications associated with minimally invasive lateral interbody fusion, comparing prepsoas with transpsoas approaches, the authors found that the incidence rate of hematoma to be 1.5% (in 1,398 patients) and 1.7% (in 1,198 patients) respectively, without statistical significance.²⁷

The balance between bleeding and administration of anticoagulation therapy is challenging during peri-operative period, especially in older patients with multiple co-morbidities. The risk of development of iliopsoas hematoma after anticoagulation therapy has been discussed by multiple authors.^{1,28,29} Sarwat et al reported a case of a 31-year-old female with intractable lower back pain, who underwent a dynamic stabilization procedure from L3 to L5. Post-operatively she received prophylactic anticoagulants. On the 3rd post-operative day she developed left groin pain and numbness in the thigh without motor deficit. MRI showed iliopsoas hematoma, for which they decided drainage under CT guidance.³⁰ Others found that the incidence of spontaneous iliopsoas hematoma to be 3.8 cases per 1,000 admissions to intensive care units. They included 40 patients on either prophylactic or therapeutic anticoagulation, with more than half of them required embolization.²⁸ In our case, the patient had no coagulopathy and no active bleeding during surgery. Our assumptions for the hematoma could be either due to post-operative prophylactic anticoagulation or pre-operative use of anti-platelets. Up to our knowledge, very few papers discussed the possible effect of pre-operative anti-platelets on the risk of development of iliopsoas hematoma.

The decision to drain or observe iliopsoas hematoma remains controversial. Despite the large collection in our case, conservative management with close observation was undertaken. Most of iliopsoas hematomas are managed conservatively if there was no clinical and hemodynamic deterioration.^{1,31} This can include stopping anticoagulants, fluid and blood administration and close observation with monitoring of hemoglobin and coagulation profile.³² However, surgical intervention is recommended by others in case of hemodynamic instability despite resuscitation and neurological deficit.³³ Our patient had stable vital signs and hemoglobin level without coagulopathy post-blood transfusion. These factors guided conservative management together with the decisions of the primary team, general surgery team and medical teams to proceed with conservative management.

Conclusion

Iliopsoas hematoma following spinal surgery is considered a rare complication. Other causes should be investigated including post-operative anticoagulation and pre-operative use of antiplatelets therapy. Conservative management should be considered in case of stable hemodynamic patients with non progressive collection. Complete resolution of iliopsoas hematoma in our case on follow-up CT scans and femoral nerve palsy postulate that, even in cases of large hematomas, conservative management should be considered.

Ethical Approval

The study was approved by institutional review board by King Faisal Specialist Hospital & Research Center.
