Purpose: The aim of this study is to investigate the relationship between childhood maternal level of education (CMLE) and changes in anthropometric and laboratory risk markers of metabolic syndrome (MetS) in mid-adulthood using results from the 1958 British Birth Cohort Study.

Design: Cohort study.

Participants: A total of 9376 study samples consisting of subjects that participated in the biomedical survey of the national child development study (NCDS) carried out between 2002 and 2004 were used for the analysis.

Main Outcome Measures: Five risk markers of MetS: (i) HDL-cholesterol (ii) triglyceride (iii) blood pressure (BP) including systolic (SBP) and diastolic (DBP) (iv) waist circumference (WC) and (v) glycated haemoglobin (HbA1c).

Methods: The NCDS or the 1958 British birth cohort data deposited in the UK data service by the centre for longitudinal studies were used for analyses. Ordinary least squares regression was used to determine unit changes in the outcome variables given CMLE.

Results: The estimates for unadjusted regression analysis of individual risk markers indicated a significant relationship between CMLE and alterations in the five risk markers of MetS (HDL-cholesterol, triglyceride, WC, HbA1c, and BP) in midlife. After adjustment for birth and lifestyle characteristics/health behaviours, the relationship between CMLE and the risk markers was attenuated for HDL-cholesterol, triglycerides, and HbA1c but remained significant for WC 0.70 (95% confidence interval (CI) 0.065–1.30, $p < 0.001$) and SBP 1.48 (95% CI 0.48–2.47 $p < 0.001$).

Conclusion: There was a positive association between lower CMLE and the risk of MetS using the NCDS data. Lifestyle characteristics may be influential determinants of MetS risk in mid-adulthood.

Keywords: maternal education, metabolic syndrome, risk markers, biomedical survey, NCDS data

Introduction

Metabolic syndrome (MetS) is generally defined as a clustering of cardiometabolic abnormalities including central obesity, hypertension, dyslipidaemia, hyperglycaemia, and insulin resistance with central obesity.¹ These metabolic disorders are significant risk factors for MetS and cardiovascular disease (CVD) generally regarded as the primary clinical outcome.² The risk factors of MetS, as defined

by the National Cholesterol Education Program (NCEP) Adult Treatment Panel III (ATP III) criteria,³ are recurrent features in the aetiology of many non-communicable diseases.⁴ Their importance in the health and wellbeing of an individual or group cannot be overemphasised as changes in these risk factors are responsible for a greater percentage of all death globally and are expected to cause about 80% of all deaths in 2020.^{4,5} The risk factors for MetS often develop in early childhood and are maintained over a life-course. The multifactorial origin of MetS will be well understood if the risk factors are analysed individually in relation to socioeconomic status (SES).⁶ SES and behavioural factors such as alcohol consumption, exercise frequency and smoking status can lead to changes in these risk factors resulting to chronic disease conditions.^{7–10} Parental level of education as an indicator of SES has been found to be an important marker for characteristics that are related to increased risk of MetS, such as limited access to health facilities and treatment, physical stress, and lack of motivation to engage in activities that are beneficial to health.⁶

The aim of this study is to investigate the relationship between CMLE and anthropometric and laboratory risk markers of MetS including WC, BP, triglycerides, HDL-cholesterol and glycated haemoglobin (HbA1c). The result is expected to show the impact of CMLE on MetS risk markers in midlife. Knowledge and understanding of the magnitude of change of these risk markers in relation to CMLE will help healthcare professionals to design an early intervention strategies on cardiometabolic health risk.

Method

This study was carried out using data obtained from a cohort of individuals born in a certain week in March 1958 who were invited to participate in a biomedical survey in 2002 (age 44). This cohort of individuals is known as the 1958 British Birth Cohort or the National Child Development Study (NCDS). An ongoing socioeconomic and health survey are being carried out on this cohort by the University of London centre for longitudinal studies. The 2002 biomedical survey, which included 9376 participants, was designed to obtain risk factors and measures which determine ill-health, with the aim of establishing, through exploration, the influence of child development, environment, and lifestyle on ill health. In addition, the survey was intended to help researchers address a wide range of issues relating to

cardiovascular health, anthropometry, visual and hearing impairment, allergic and respiratory disease, and mental health. Furthermore, the survey will help researchers to understand the psychological and physiological functions among adults in their midlife.

Maternal Level of Education

In England and Wales, the Law states a minimum age for a child to stay in full-time education. The Education Act of 1996 made it an obligation for parents to have their children in full-time education from the age 5 to 16,¹¹ although the attendance of school is not compulsory, as section 2 of the act allows for home schooling. The minimum compulsory school leaving age of 16 came into force in 1972.¹² This was preceded by the Butler Education Act of 1944 which came into force in 1947 and the Fisher Education Act of 1918 which was enforced in 1921.^{13,14} The 1944 Act raised the minimum school leaving age from 14 to 15 years¹⁵ and the 1918 Act made it compulsory for children to be in full-time education from age 5 to 14 years.¹³

In this study, CMLE was derived from the provisions of the 1918 and 1944 Education Act. The two Education Acts were enforced prior to 1958 when the first NCDS survey was carried out, implying that the parents of the cohort members left compulsory education at age 14 or 15. The CMLE variable was dichotomised to “leaving full time education at or before minimum school leaving age” and “staying in full time education after minimum school leaving age”. The cohort members whose mothers left school on or before minimum school leaving age were categorised as low CMLE and the participants whose mothers were in compulsory education after the minimum school leaving age were categorised as high CMLE.

Outcome Variables

In the 2001 NCEP ATP III definition,³ an individual is said to have MetS if he/she presents at least 3 of the 5 risk factors: (1) abdominal obesity and WC greater than 102 cm for men and 88 cm for women, (2) low HDL cholesterol (<40 mg/dL or 1.04 mmol/L for men and <50 mg/dL or 1.3 mmol/L for women), (3) elevated triglyceride (≥ 150 mg/dL or 1.7mmol/L), (4) elevated BP (>130 mmHg for SBP and >85 mmHg for DBP), and (5) elevated fasting glucose (FG) (≥ 110 mg/dL). In this study, glycated haemoglobin (HbA1c) was used in place of FG as the hyperglycaemic component in the diagnosis of MetS. Due to the nature of the survey and the considerably large

sample size, it would have been challenging and very complex to obtain an accurate FG from this group of participants. The ATP III criteria did not require evidence of insulin resistance for diagnosis of MetS. Like the WHO criteria, ATP III allowed for diagnosis of MetS if type 2 diabetes is present because of the high risk of CVD among patients with type 2 diabetes.

WC was measured using body tension tape. Everyone was eligible for the measurement except those who did not consent, and pregnant women. The equipment used for measurement of blood pressure was an OMRON 97 blood pressure monitor with standard and large cuffs for adults. The measurements were taken by trained nurses, and pregnant women were excluded. Three outcome measures HbA1c, HDL-Cholesterol and triglyceride were derived from blood samples. A non-fasting venous blood sample was collected by nurses in four separate Sarstedt polypropylene tubes containing (i) EDTA anticoagulant, sent to St George's Hospital for processing, (ii) citrate anticoagulant, sent to Royal Victoria Infirmary, Newcastle for processing, (iii) no anticoagulant, sent to Royal Victoria Infirmary, Newcastle for processing, and (iv) CPDA anticoagulant, sent to ALPAC Laboratory, Bristol for processing. The tube that contained no anticoagulant was used to analyse triglycerides and HDL-Cholesterol with serum supernatant obtained after centrifuging the blood sample. The measurement for triglyceride and HDL-Cholesterol was done using an Olympus model AU 640 auto-analyser. 0.5 mL of blood in the tube that contained citrate was analysed for glycated haemoglobin (HbA1c). The blood sample was measured for HbA1c by ion exchange high chromatography using the Tosoh Alc 2.2 Glycohaemoglobin Analyser HLC-723GHB. In this study, the value of HbA1c is expressed as a percentage Diabetes Control and Complication Trial unit.¹⁶

Confounding Variables

The first step in data analysis was to identify and select the variables that would be included in the model used to address the research questions. The aim of this study was used to determine the choice of the outcome variables and independent variables of interest. The candidate variables were manually identified based on the knowledge and information obtained from prior studies.^{8,17–22}

To effectively estimate the association between CMLE and MetS in midlife, confounding factors were included in the analysis. The confounders were placed in 2 groups. The first group consisted of characteristics that were

observed in childhood. These were gender (male, female), maternal age at birth (years), birth weight (kilograms), breastfeeding (no, under one month, over one month) and father's social class (non-manual, manual). The second group of confounding factors were lifestyle characteristics and health behaviours in adulthood. These were smoking at age 42 (current smoker, ex-smoker, never smoked), alcohol frequency (infrequent/never, daily, weekly, monthly), exercise frequency (regular, some days, little or less often), fruit consumption (daily some days, occasionally, never), sweet consumption (daily, some days, occasionally, never), and BMI (moderate/not obese, highly obese).

Handling of Missing Data

Multiple imputation by chained equations was used to handle missing data in the independent and outcome variables. The number of imputations used was 10, meaning 10 imputed data sets were created. The imputed datasets were examined to see if the imputation appeared reasonable by checking if the standard deviations of the imputed datasets appeared similar. Before the primary analysis, the fit of the imputation model was checked to compare the imputed values with observed values to check for implausible imputed values prior to analysis. For categorical variables, graphs and tables of proportion of frequencies were used. Due to issue with data distribution, the variable that indicates triglyceride was log transformed prior to analysis.

Statistical Analysis

Descriptive statistics were generated to get sense of the data and to help to summarise and understand the characteristics of the study population and relationships between variables. The descriptive statistics were used to compare the frequency and relative frequency of the categorical variables in relation to CMLE for both male and female participants. They were used to compare the mean of the outcome variables in relation to CMLE for both male and female participants. An exploratory two-sample *t*-test was used to help give insight on the outcome variables. A two-sample *t*-test between high and low CMLE was computed for each of the 5 risk markers of MetS, to test the null hypothesis that there was no difference in risk markers of MetS between high and low CMLE groups. Participants grouped in relation to their CMLE were compared based on the average level of markers of MetS. Before comparing the groups using *t*-tests, the data was

checked to ensure it met the assumptions of the *t*-test. This was done using box plots, normal quantile plots and tests to indicate whether variance in the outcome variable was significant among the groups (high and low CMLE).

The associations between CMLE and each of the five risk markers of MetS were estimated using ordinary least squares regression (OLR) linear regression. Four models were fitted for each risk marker. In model 1, the crude, or unadjusted, associations between CMLE and each of the five risk markers were estimated. In model 2, the confounding effect of characteristics at birth was explored. Model 3 involved examining the influence of lifestyle characteristics and health behaviours on the associations between CMLE and each of the MetS risk markers. In model 4, the overall effects of birth and lifestyle characteristics and health behaviours were explored. The results obtained for transformed outcome variable (triglyceride) were recorded as percentage difference.

Results

Table 1 shows the characteristics of study participants at baseline. Apart from missing values and non-response, the data used for the analysis contained 4330 male and 4363 female participants. Of these numbers, 27% of males were classed as high CMLE and 73% as low CMLE. Similar proportion as male for high and low CMLE was observed for female participants. The mean level of HDL-cholesterol, WC, SBP, DBP, and HbA1c tended to be higher in participants with low CMLE than those with high CMLE. About 80% of male and 90% of female participants classed as low CMLE were born to parents that belong to the manual occupation social class. For high CMLE only 43% of male and 45% of female participants were born to parents in manual occupations. The proportion of participants that smoked was higher for low CMLE compared to high CMLE. Similarly, participants classed as low CMLE were shown to be more obese than those with high CMLE.

Table 2 presents the results of two-sample *t*-tests. The results show that the average HDL-cholesterol for male participants with high CMLE was 1.46 mmol/L, compared to 1.43 mmol/L for those that had low CMLE. The difference in mean was 0.03 mmol/L, which is significantly different from zero with a two-tailed *p* value of 0.001. This implied that male participants with high CMLE were in significantly better health than those with low CMLE. A similar result was recorded for female participants. The mean difference in waist circumference for female participants between high and low CMLE groups was -2.60

mmol/L. The two-tailed *p* value was 0.001, indicating that there was a difference in WC between high and low CMLE for female participants. This showed that female participants classed as low CMLE were more likely to have a larger WC than those classed as high CMLE.

In Table 3, the crude (unadjusted) regression analysis showed a significant relationship between CMLE and all risk markers of MetS in model 1. These relationships did not change in model 2. This means that the inclusion of the childhood confounding factors of gender, maternal age at birth, birth weight, breastfeeding, and father's social class did not impact on the relationship between CMLE and the risk markers of MetS. In model 3, there was a significant relationship between CMLE and all risk markers of MetS except HbA1c after adjustment for the confounding lifestyle characteristics/health behaviours of smoking at age 42, alcohol frequency, exercise frequency, fruit consumption, sweet consumption, and BMI. A coefficient of -0.04 (95% CI, -0.06, -0.01, *p*<0.001) indicated that HDL-cholesterol decreased by 0.04 mmol/L in participants with low CMLE compared to those with high CMLE. Similarly, low CMLE resulted in increased WC of 1.20 cm (95% CI 1.27, 2.54, *p*<0.001) compared to high CMLE. After adjustment for birth and lifestyle characteristics/health behaviours, the relationships between CMLE and the risk markers were significant for waist circumference and blood pressure but not for triglyceride, HDL-cholesterol, and HbA1c. On average, participants in the low CMLE group had 0.70 cm (95% CI 0.065, 1.30, *p*<0.001) increased WC compared to those with high CMLE, if birth and lifestyle characteristics and other factors indicating health behaviours were kept constant. An increased level of SBP of 1.48 mmHg (95% CI 0.48, 2.47 *p*<0.001) was recorded in participants with low CMLE compared to those with high CMLE.

Discussion

In this study, we have analysed the association between CMLE as a measure of SES and risk markers of MetS. The results of the regression analysis for the crude estimates indicated a significant association between CMLE and the five risk markers for MetS. The association stays the same after adjustment for characteristics at birth. The overall adjustment for birth characteristics and lifestyle factors showed that WC and blood pressure (systolic and diastolic) were significantly related to CMLE. Although several published studies have looked at the relationship between socioeconomic indicators of MetS in adulthood, to our

Notes: Data are $\pm$ standard deviation (sd) or absolute numbers (%), n = the number of sample and the proportion or percentage of the sample is in bracket, N = total number of sample for male or female participants grouped according to the level of education. High indicates participants whose mothers stayed in school after minimum school living age. Low indicates leaving school on or before minimum school leaving age. HDL-cholesterol, Triglyceride, Waist Circumference, Systolic BP, Diastolic BP, and HbA1c are the outcome variables. Maternal age, breast feeding, birth weight and fathers social class indicates participants characteristics during birth. Smoking at age 42, alcohol frequency, exercise frequency fruit consumption, sweet consumption and BMI represents participants lifestyle characteristics and health behaviours.

Notes: Data are $\pm$ standard deviation (sd), n = the number of samples, SE is the standard error, mean diff is the difference between the mean of high- and low-level maternal education. High indicates participants whose mothers stayed in school after minimum school living age, Low indicates leaving school on or before minimum school leaving age. HDL-cholesterol, Triglyceride (log transformed), Waist Circumference, Systolic BP, Diastolic BP, and HbA1c are the outcome variables.

knowledge this is the first study that collectively looked at the unadjusted and adjusted effects of CMLE and the level of risk markers of MetS using NCDS data. In this study, we emphasised the crude estimates and estimates resulting from adjustment due to birth characteristics and lifestyle and health behaviours in midlife.

CMLE and Lipid Profile

An individual's lipid profile is mainly defined by the cholesterol and triglyceride level. In this study, CMLE was found to be related with changes in the level of HDL-cholesterol and triglycerides in midlife. The results of the unadjusted regression analysis and those that

Table 3 Association Between Childhood Maternal Level of Education and Metabolic Syndrome in Mid-Adulthood

Notes: Table 3 represents unstandardised coefficient which expresses the change in outcome due to change from low to high CMLE adjusted for characteristics at birth, lifestyle characteristics and health behaviours. Model 2 was adjusted for "gender", "mothers age at birth", "birthweight", "breastfeeding"; and father's social class'. Model 3 was adjusted for gender', 'smoking at age 42', "alcohol frequency", "exercise frequency"; fruit', "sweet", 'BMI'. Model 4 was adjusted for education', "gender", 'mothers age at birth', "birthweight", "breastfeeding"; father's social class', 'smoking at age 42', "alcohol frequency", "exercise frequency"; fruit', "sweet", 'BMI'. The confidence interval is in parenthesis. *** p<0.01, ** p<0.05, * p<0.1.

involved separate adjustment for birth and lifestyle characteristics and health behaviours indicated a significant relationship between low CMLE and HDL-cholesterol. The significant relationship between CMLE and the blood lipid profile in terms of HDL-cholesterol and triglycerides was attenuated after overall adjustment for a combination of birth and lifestyle characteristics and health behaviours. Although CMLE may have a direct influence on the blood lipid level, other birth characteristics and lifestyle factors may exact more effect on the lipid level. Also, triglyceride concentration in the blood may be less stable due to the effects of recent meals. This is the reason why researchers normally require 12 hours of fasting before taking blood samples.²³

The findings in this study were consistent with past studies that aimed to establish the association between individual educational level or maternal education and lipid profiles, especially HDL cholesterol and triglycerides.^{23–27} Some studies reported findings similar to this study, while the direction of the association between education and lipid profiles in some studies was opposite to in this study.^{28–30} A possible explanation for the association between lower education level and lipid profile

may be that participants whose parents are well educated are more likely to consume fruit, vegetables and food with less saturated fat.^{31,32} Selecting a diet with low saturated fat for a child was found to lead to an improved plasma lipid profile and will help to reduce atherosclerotic vascular disease over a life course.³³ This was evidenced in some animal studies that showed that atherosclerosis was highly likely to develop in species of animal that are fed with diets that increase total and low-density lipoprotein level in the blood.^{34–37} Furthermore, in adults and children across many countries, the differences in lipid profile are determined by the amount or proportion of saturated fat in the diet.^{38,39}

CMLE and HbA1c

The result of the regression analysis showed that CMLE was associated with the risk of type 2 diabetes in midlife. The association became attenuated when adjusted for lifestyle characteristics and health behaviours in midlife. These findings were consistent with the results of past studies that indicated that children born to less educated parents are in a disadvantaged position which increases the risk of diabetes in midlife,^{40–45} although some of these

findings were weak when study sample size, participants' gender and methodological designs were considered. In terms of gender, some past studies on the association between indicators of childhood SES and diabetes reported either weak or no association between maternal education and diabetes in men.^{40,43,45} Similarly, in other studies, the association between incidence of diabetes and childhood socioeconomic position was weak in women and there was no association in men.^{41,44}

CMLE and WC

A significant result was recorded for the association between CMLE and WC. The unadjusted estimates indicated a significant association between CMLE and WC. After adjustment for birth and lifestyle/health behaviours the relationship stayed the same. Participants that had low CMLE were found to be more obese than those with high CMLE. The proportion of female participants with large WC was higher than the proportion of males. The findings in this study are in line with other studies that found that the educational level of parents has an impact on the weight of their offspring.^{46–48} Obesity is a key risk factor for many chronic health conditions. Unusual weight in adulthood could be a result of parental characteristics during childhood which, according to some studies, determine health outcomes in adulthood.^{47,49,50} Large WC, which signifies obesity, affects the body as a whole, including the cardiovascular and respiratory systems.^{51,52} It also impacts on the physiological, health and cognitive behaviours of an individual. Compared to paternal characteristics, maternal characteristics were found by many studies to have a stronger effect on the health behaviours and health status of children.^{49,53} CMLE is a strong determinant of children's health behaviours. Mothers with a lower level of education tend to feed their children more unhealthy food, which may negatively impact their health and wellbeing.^{49,50,54,55} The habits of unhealthy eating formed during childhood may be difficult to drop in adulthood. This could influence changes in body weight from childhood to adulthood.

The findings from this study should spur health professionals to design measures that will target different maternal levels of education. Strengthening the health education of mothers will help them to understand the benefits of proper nutrition and weight management in children.⁵⁶

CMLE and Blood Pressure

Both crude and adjusted estimates indicated a significant association between CMLE and blood pressure in midlife.

The association between CMLE and blood pressure established in other studies has been confirmed in this study.^{57–}

⁵⁹ A possible explanation lies in the life course model, which suggests that early disadvantages in terms of SES could have effects on blood pressure through several mechanisms at each stage of life.⁶⁰ In addition, it has been confirmed by some studies that the risk factors for atherosclerosis in adults are similar to those in childhood.^{61–63} Elevated blood pressure, which is one of the risk factors for atherosclerosis, is common in children in disadvantaged socioeconomic positions. Children born to mothers with lower levels of education are in a disadvantaged position⁶⁴ due to the prevalence of some health behaviour risk factors, such as lack of physical exercise, high intake of dietary sodium and obesity, which have adverse effects on blood pressure.^{65–68} These health behaviours acquired during childhood often persist into adulthood. The effect of elevated blood pressure in childhood might lead to increased blood pressure in adulthood, as individuals with high blood pressure in childhood are more likely to have elevated blood pressure in adulthood, and vice versa.⁶⁹ Therefore, the early stages of life seem to be critical for hypertension and cardiovascular abnormalities in adulthood.^{70,71}

Prevention of hypertension in adulthood should start as early as possible and should aim at modification of lifestyle factors including increasing physical activity, reducing sodium in the diet, body weight management and frequent consumption of fruit, vegetables, fibre and low-fat dairy.

Strengths and Limitations

The survey sweeps and biomedical survey of the NCDS are prospective in nature. As a result, "recall bias" is not a major issue in this kind of study. A recall bias is said to occur when participants give inaccurate or questionable accounts of an event during an interview.⁷² The outcome measures such as HDL-cholesterol, triglyceride, HbA1c, WC and blood pressure used in this study were obtained directly from participants by qualified professionals and did not require participants to recall any value which could lead to inaccurate results. In addition, the issue of measurement bias⁷³ was minimised because values recorded for measures such as WC and blood pressure were obtained from the average of 3 measurements taken at specified time intervals. Also, the outcome measures obtained from the blood sample, including HDL-cholesterol, triglyceride, and HbA1c were obtained from laboratory analysis with no interference from participants

or researchers. Over 90% of participants had English as their first language; therefore, instructional materials and guidelines relating to each survey sweep was assumed to be well understood.⁷⁴ Multiple imputation was used to handle missing data. Under a missing at random (MAR) assumption, data were imputed for missing values in both independent and outcome variables. The results of both multiple imputation and complete case analysis were similar when compared. The multiple imputation results in increased sample size and less bias in the result. In terms of limitation, HbA1c was used as a risk marker of MetS instead of fasting glucose because it was easier to obtain from participants. T results may be different if FG was used.

Data Sharing Statement

The datasets analysed during the current study are available in the UK data service repository, <https://www.ukdataservice.ac.uk/get-data>. The NCDS biomedical survey data is made available by applying for a special license to UK Data Service.

Ethics Approval

This study was approved by the research ethics committee of the University of Bedfordshire (No. IHREC828) to carry out this research. A special license (No11906) for NCDS biomedical survey data was granted by the UK Data service.

Acknowledgments

The authors thank the UK Data Service and Centre for Longitudinal Studies for granting a special license to use NCDS biomedical data. The authors are also grateful to the Research Ethics Committee of the University of Bedfordshire for approval to carry out this study.

Author Contributions

All authors made substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; took part in drafting the article or revising it critically for important intellectual content; agreed to submit to the current journal; gave final approval of the version to be published; and agree to be accountable for all aspects of the work.

Funding

There is no funding to report.
