Abstract: Transgenic liver-specific inactivation of the carcinoembryonic antigen-related cell adhesion molecule (CEACAM1) impairs hepatic insulin clearance and causes hyperinsulinemia, insulin resistance, elevation in hepatic and serum triglyceride levels, and visceral obesity. It also predisposes to nonalcoholic steatohepatitis (NASH) in response to a high-fat diet. To discern whether this phenotype reflects a physiological function of CEACAM1 rather than the effect of the dominant-negative transgene, we investigated whether Ceacam1 (gene encoding CEACAM1 protein) null mice with impaired insulin clearance also develop a NASH-like phenotype on a prolonged high-fat diet. Three-month-old male null and wild-type mice were fed a high-fat diet for 3 months and their NASH phenotype was examined. While high-fat feeding elevated hepatic triglyceride content in both strains of mice, it exacerbated macrosteatosis and caused NASH-characteristic fibrogenic changes and inflammatory responses more intensely in the null mouse. This demonstrates that CEACAM1-dependent insulin clearance pathways are linked with NASH pathogenesis.

Keywords: nonalcoholic steatohepatitis, CEACAM1, high-fat diet, inflammation, apoptosis, fibrosis

Introduction

Nonalcoholic fatty liver disease (NAFLD) constitutes a spectrum of diseases ranging from benign hepatic steatosis to chronic nonalcoholic steatohepatitis (NASH) and cirrhosis. The incidence of nonalcoholic fatty liver disease (NAFLD) is on the rise worldwide, in part due to the increase in obesity.1 The prevalence of NAFLD in the United States is currently estimated at ~20%–25%, and in the morbidly obese population, at ~75%–90%. NASH, its progressive form, is estimated to be present in ~3%–5% of the general population.2,3 Of these, ~3%–5% have progressed to cirrhosis, including those with end-stage liver disease and/or primary liver cancer.4,5

Despite intense research efforts, mechanisms of the etiology and progression of NAFLD remain poorly understood. This could be due in part, to the limitation of the experimental animal models, which have been used to study the pathogenesis of the disease.6,7 Clearly, NAFLD is multifaceted and includes both genetic and environmental factors.7 It is generally agreed that visceral obesity and dysregulation in lipid metabolism and hepatic immune response are involved in progression to NASH.8 Although it is likely that NAFLD shares common pathophysiology with type 2 diabetes and metabolic syndrome, the role of insulin resistance in its pathogenesis remains controversial.9,10

Upon phosphorylation by the insulin receptor, carcinoembryonic antigen-related cell adhesion molecule 1 (CEACAM1) promotes receptor-mediated insulin endocytosis...
and degradation in the hepatocyte, the main mechanism of insulin clearance in the liver. Mice with liver-specific dominant-negative transgenic inactivation of CEACAM1 (L-SACC1) and mice with global null mutation of the Ceacam1 gene (Cc1-) develop insulin resistance due to impaired hepatic insulin extraction and hyperinsulinemia. Chronic hyperinsulinemia results in increased hepatic lipid production and output followed by substrate redistribution to white adipose tissue and visceral obesity.

We have recently shown that L-SACC1 mice develop spontaneous hepatic fibrosis, which becomes more intense when the mice are fed a high-fat (HF) diet for 3 months. Moreover, other key features of NASH (inflammation, oxidative stress, and apoptosis) are induced by sustained HF intake. This could be due to complete loss of function of CEACAM1 or to the inability of the transgene-encoded protein to become phosphorylated. To gain further insight into the role of CEACAM1 in the etiology and progression of NAFLD, we have assessed the effect of whole body Ceacam1 gene deletion on the pathogenesis of NASH in response to HF feeding. We herein report that Ceacam1 null mice (Cc1-) exhibit key features of obesity-related NASH when fed a HF diet for three months.

Materials and methods

Cell culture

Cc1-/- mice were backcrossed twelve times onto the C57BL/6 (BL6) genetic background, kept in a 12-hour dark/light cycle and fed a standard chow, ad libitum. All procedures were approved by the Institutional Animal Care and Utilization Committee. Three-month-old male mice were fed ad libitum either a standard chow (2016 Teklad, Harlan Laboratories), low fat (12%) regular diet (RD) or a 45% HF diet (Research Diets, Catalog #D12451, New Brunswick, NJ) for 3 months prior to sacrifice and phenotypic characterization.

Metabolic analysis

Following an overnight fast, mice were anesthetized with sodium pentobarbital at 1100 h. Whole venous blood was drawn from the retro-orbital sinuses to measure serum insulin by radioimmunoassays (Linco Research, St Charles, MO), serum-free fatty acids (FFA) by NEFA C kit (Wako Diagnostics), respectively, and serum triglycerides by Infinity® Triglycerides reagent ( Sigma, St Louis, MO). Hepatic total cholesterol and free cholesterol were measured using Infinity™ cholesterol reagent (Thermo Electron, Waltham, MA) and free cholesterol reagent (Wako Diagnostics), respectively, and triglyceride content, as described previously. Visceral adipose tissue was excised and weighed and visceral adiposity expressed as percentage of total body weight.

Liver histology

Formalin-fixed, paraffin-embedded liver sections were stained with hematoxylin-eosin (H&E) and assessed for the degree of steatosis and lobular inflammation according to the NASH scoring system recently proposed by the NIDDK-NASH Clinical Research Network. Fibrosis was assessed on deparaffinized and rehydrated slides in 0.1% solution of Sirius Red (Sigma, Direct Red 80, St Louis, MO). TUNEL assay was performed using the ApopTag Plus Peroxidase Apoptosis Detection Kit (Chemicon International, Temecula, CA). Tissue sections on the other half of the same slide served as controls without terminal deoxynucleotidyl transferase (TdT) enzyme following digestion with proteinase K to account for nonspecific binding of enzyme conjugate.

Glutathione assay

Liver concentrations of reduced glutathione (GSH) were assayed using the Bioxytech® GSH-400 kit (OXISResearch, Portland, OR), as previously done.

Western analysis

Tissue lysates or serum (for apolipoprotein B [ApoB]) were analyzed by 4%–12% gradient SDS-PAGE (Invitrogen, Carlsbad, CA) prior to Western analysis with polyclonal antibodies against caspase 3 (Cell Signaling Technology-Cat#9662, Beverly, MA), ApoB48/100 (Chemicon International, Temecula, CA), fatty acid synthase (FAS), Niemann Pick type C1 (NPC1) (Abcam, Cambridge, MA), p65 NF-kB phosphoserine (Ser 536) and p65 NF-kB (Cell Signaling Technology, Beverly, MA), as previously done. For normalization, membranes were reprobed with monoclonal antibodies against RPS3 (ProteinTech Group, Inc., Chicago, IL) and α-actin (Sigma). All blots were incubated with horseradish peroxidase-conjugated anti-IgG antibody prior to protein detection by enhanced chemiluminescence (ECL; Amersham Pharmacia Biotech, Piscataway, NJ) and quantification by densitometry and Image J software (v. 1.40, NIH).

Semiquantitative real time polymerase chain reaction-based gene expression

Total RNA in the liver was isolated with PerfectPure RNA Tissue Kit (5 Prime, Gaithersburg, MD) and total RNA in the adipose tissue was isolated with RNeasy Lipid Tissue Mini...
Kit (Qiagen, Valencia, CA) according to the manufacturer’s protocol. cDNA was synthesized using ImProm-II™ Reverse Transcriptase (Promega, Madison, WI) using 1 µg of total RNA and primers for lipid catabolism, fibrosis and inflammatory markers, and as reference control, glyceralddehyde 3-phosphate dehydrogenase (GAPDH) (Table 1). cDNA was evaluated with real-time quantitative polymerase chain reaction (StepOnePlus™; Applied Biosystems, Foster City, CA). The relative amounts of mRNA were calculated by comparison to the corresponding standards and normalized relative to GAPDH. Results are expressed in fold change as mean ± SEM.

Statistical analysis
Data were analyzed with SPSS software using one-factor analysis of variance (ANOVA) and graphed with GraphPad Prism 4 software. P < 0.05 was statistically significant.

Results
High-fat diet alters hepatic insulin and lipid metabolism in Ccl1−/− null mice
As previously reported,19,20 6-month-old male Ccl1−/− mice exhibited visceral obesity and hyperinsulinemia (Table 2). Consistent with increased visceral obesity, they also developed elevated serum levels of leptin and FFA (Table 2). HF feeding for 3 months induced serum insulin levels by ∼2-fold in both strains of mice (Table 2).

Western analysis revealed hepatic FAS protein was ∼2-fold higher in null than wild-type mice, regardless of diet (Figure 1a). This could contribute to the significantly higher hepatic triglyceride content in RD-fed null mice (Table 2). Sustained HF intake induced hepatic triglyceride level in both mouse strains, but decreased serum triglyceride in Ccl1+/−null mice (Table 2). The lower gain in adiposity in Ccl1−/−null mice in response to HF diet (1.5- versus 3-fold increase in Ccl1+/−wild-type mice from the same genetic background [Table 2]) suggests that the lower serum triglyceride in Ccl1−/−null mice was due to a reduction in hepatic triglyceride output. This notion is, in part, supported by the lower serum ApoB100/ApoB48 protein levels in HF-fed null compared to wild-type mice (Figure 1b).

Liver total and free cholesterol were comparable in both mouse strains on the low-fat regular diet. Total cholesterol was increased ∼4-fold in both on the HF diet, with the increase due to increased cholesterol esters (Table 2). The protein level of hepatic NPC1, a late endosomal cholesterol traffic protein, was decreased ∼50% by HF diet in null, but not wild-type mice (Figure 1a). Consistently, hepatic GSH content in Ccl1−/−mice was almost half that of Ccl1+/+ mice on the HF diet (Figure 1c).

Hepatic steatosis was increased in both strains on the HF diet (Figure 2). Histological evaluation from different fields revealed that fat infiltration was more diffuse in livers from Ccl1−/−as compared to Ccl1+/+wild-type mice (panel 4 versus 2), which showed fat-free parenchyma alternating with affected areas. In HF-fed Ccl1−/−null mice, the steatosis appeared to be predominantly macrovesicular in addition to microvesicular hepatocyte fat accumulation. However, the HF-fed wild-type Ccl1+/+livers exhibited predominantly microvesicular steatosis with a mix of macrosteatosis. No ballooning injury of the hepatocyte was noted.

Abbreviations: GAPDH, glyceraldehyde 3-phosphate dehydrogenase; PPARα, peroxisome proliferator-activated receptor α; CYP2E1, cytochrome p450 enzyme; TNFα, tumor necrosis factor-α; TGFβ, transforming growth factor-β; IL-6, interleukins; IFNγ, interferon gamma; TGFβ, transforming growth factor-β.
High-fat diet induces an inflammatory response in liver and adipose tissue of Ccl1−/− null mice

H&E staining of liver sections revealed few inflammatory islands with no significant change in hepatic cellular architecture in both strains of mice on the RD (Figure 2, panels 1 and 3). Upon HF feeding, Ccl1+/+ wild-type mice showed occasional foci of inflammatory cells, mostly periportal (Figure 2, panel 2 and Figure 3a, left panel), as opposed to Ccl1−/− null mice, which exhibited multiple foci of inflammatory cell infiltrates in the hepatic lobules, as well as in the periportal areas (Figure 2, panel 4 and Figure 3a, right panel). Consistently, HF diet activated nuclear factor kappa-light-chain-enhancer of activated B cells (NF-κB) to a higher extent in Ccl1−/− than Ccl1+/+ livers, as indicated by a ~10-fold versus ~1.5-fold increase in NF-κB phosphorylation (Figure 3b).

Consistent with macrophage recruitment to white adipose tissue (WAT) in visceral obesity,22 RD-fed Ccl1+/+ null mice exhibited higher F4/80 and tumor necrosis factor-α (TNFα) mRNA levels in their WAT than their wild-type counterparts, as assessed by semiquantitative reverse transcription polymerase chain reaction (RT-PCR) analysis (Table 3). Similarly, hepatic TNFα mRNA content is elevated in the Ccl1−/− null mouse. This could derive from resident hepatic macrophages, the population of which appeared to be elevated based on the higher F4/80 mRNA content in Ccl1−/− mouse liver (Table 3), in addition to hepatic WAT infiltrates. Sustained HF diet induced a further increase in the macrophage pool (F4/80) and TNFα mRNA content in WAT and liver of both groups of mice (Table 3).

mRNA content of CD4 was elevated in RD-fed Ccl1−/− null mice and remained elevated without further increase in response to HF diet (Table 3). This suggests basal elevation in CD4+ T cell pool in null mice. Hepatic mRNA content of transforming growth factor β (TGFβ) and interferon-gamma (IFNγ) followed a similar change. Elevation in basal IFNγ, but not interleukin (IL)-4/IL-13 mRNA levels, suggests a CD4+ Th1, but not CD4+ Th2 response, in RD-fed Ccl1−/− mouse livers.

In agreement with the small degree of periportal inflammation in HF-fed Ccl1+/+ wild-type mice (Figure 3a, left panel), HF diet induced hepatic mRNA levels of proinflammatory TNFα and IFNγ cytokines (Table 3).

High-fat diet causes apoptosis in Ccl1−/− null mice

Excessive fatty acid β-oxidation and lipid ω-peroxidation promote oxidative stress in obesity.23,24 Consistently, semiquantitative RT-PCR analysis revealed higher hepatic mRNA levels of peroxisome proliferator-activated receptor α (PPARα) in RD-fed Ccl1+/+ null than Ccl1−/− wild-type mice, and a further increase by HF intake in both strains of mice (Table 4). This suggests that fatty acid β-oxidation was elevated in Ccl1−/− mouse liver. The mRNA levels of hepatic CYP2E1, a member of the microsomal cytochrome p450 family involved in metabolism of long chain fatty acids (lipooxygenation) and microsomal lipid ω-peroxidation, were comparable in both RD-fed mouse strains, but underwent a ~2-fold increase by HF diet only in Ccl1−/− null mice (Table 4). Thus, it is likely that HF induced oxidative changes in the null mouse,25 which in the presence of high TNFα levels, predispose to cell death.26 Consistently, Western analysis (Figure 4a) revealed higher caspase 3 cleavage in HF-fed Ccl1−/− liver than other groups of mice. In addition to TUNEL

Notes: Male mice (n > 7; 3 months of age) were fed RD or HF for 3 months. Mice were fasted overnight and the serum and tissues removed and analyzed. Values are expressed as mean ± SEM. *P < 0.05 HF versus RD; **P < 0.05 Ccl1−/− versus Ccl1+/+ in the same feeding group.

Abbreviations: Ccl1+/+; global Cc1 mouse; Ccl1−/−; wild-type mouse from the same genetic background as Ccl1−/− mice; RD, regular diet; HF, high-fat diet; TG, triglyceride; FFA, free fatty acids.
stain (Figure 4b, panel 2 versus 1), this reveals enhanced apoptosis in HF-fed null, but not wild-type mice.

Evaluating total NAS score from H&E liver sections based on three histological features (steatosis, inflammation and ballooning) following the Kleiner's scoring system, indicated that HF-fed Cc1−/− mice developed NASH (NAS score of −5), as opposed to the other groups, which scored <2.75 (Table 5).

Development of early fibrosis in Cc1−/− null mice

In NASH, fibrosis usually starts in zone 3 as perivenular and/or pericellular fibrosis, a pattern referred to as "chicken wire" fibrosis. Sirius red stain revealed a "chicken wire" pattern of collagen deposition in Cc1−/− (stage 2), but not Cc1+/− wild-type mice on the regular diet (Figure 5, panel 3 versus 1), in spite of elevated levels of the proinflammatory IFNγ cytokine, which decreases collagen synthesis. Consistent with the profibrogenic effect of IL-6 cytokine and TGFβ, the mRNA content was higher in the liver of Cc1−/− than Cc1+/+ mice on the regular diet (Table 3). Sustained HF feeding exacerbated these fibrogenic changes in Cc1−/− mice (panel 4 versus 3) without causing further changes in IL-6 and TGFβ mRNA levels. Instead, HF induced serum leptin (Table 2) and hepatic TNFα mRNA levels (Table 3), which together could mediate progression of fibrosis and inflammation in NASH.

In Cc1+/+ wild-type mice, HF elevated leptin (Table 2) and hepatic TGFβ and TNFα mRNA levels (Table 3), without altering hepatic IL-6 mRNA levels (Table 3). HF induced a small increase in collagen production, as shown by Sirius red staining (Figure 5, panel 2 versus 1).

Discussion

Farrell and others have shown that similar to L-SACC1 mice with liver-specific inactivation of CEACAM1, mice homozygous for null mutation of the Ceacam1 gene on the C57BL/6 (BL6) genetic background manifest impairment of insulin clearance and hyperinsulinemia. This leads to
insulin resistance and increases transcription of lipogenic enzymes (including FAS) to promote de novo hepatic lipid production.19 On the BL6 genetic background, Cc1 null mutation causes preferential lipid redistribution to white adipose tissue and an increase in visceral obesity.10

The current studies show that sustained HF feeding of Cc1−/− mice caused lipid accumulation in hepatocytes despite increase in fatty acid β-oxidation. Similar changes are seen in L-SACC1 mice13 and human NASH.32,33 Cc1−/− mice also developed NASH-characteristic fibrosis when fed a HF diet; even on a regular chow diet, they exhibited low levels of pericellular fibrosis. In response to a HF diet, which triggers inflammation,34–36 Cc1−/− mice exhibited other key features of progressive NAFLD, including diffuse macrosteatosis, inflammation and apoptosis, and possibly oxidative changes, as suggested by increased hepatic CYP2E1 protein levels. These data provide further in vivo evidence that altered CEACAM1-dependent insulin clearance pathways can provide a link between insulin resistance and NASH development, at least in mice with a BL6 genetic component background.37 They also confirm that male BL6 mice are susceptible to developing a NASH-like phenotype.38

Cc1 null mutation did not affect total and free cholesterol content in the liver. However, reduction of NPC1 protein level in HF-fed Cc1−/− mice suggests increased partitioning of free cholesterol from cytosolic lipid droplets to mitochondria.39 This could reduce mitochondrial GSH stores40 and increase sensitivity to the cytotoxic effect of the proinflammatory cytokine, TNFα, the level of which was high in Cc1−/− livers, resulting partly from steatosis-induced changes in the inflammatory milieu.41,42 Consistent with a role for TNFα-dependent activation of IKK-β in oxidative stress and inflammation,43 HF diet activated NF-xB pathways to elicit a more robust inflammatory response in Cc1−/− than Cc1+/+ mice.

Notes: Male mice (n > 7.3 months of age) were fed RD or HF for 3 months. Mice were fasted overnight, the tissues removed and gene expression assessed by semiquantitative real-time PCR analysis. Values are normalized to GAPDH and expressed as mean units ± SEM. *P < 0.05 HF vs RD; **P < 0.05 Cc1−/− vs Cc1+/+ in the same feeding group.

Abbreviations: Cc1+/+, global Ceacam1 null mouse; Cc1−/−, wild-type mouse from the same genetic background as Cc1+/+ mice; RD, regular diet; HF, high-fat diet; H&E staining, hematoxylin-eosin staining; IB, immunoblotting; reliB, reimmunoblotting.
The population of CD4+ T cells was basally higher in Cc1−/− than Cc1+/+ mice fed a regular diet. This could, at least in part, be due to Ceacam1 deletion in T cells, as suggested by increased CD4+ T cell in mice with conditional deletion of Ceacam1 in T cells, but not in regular Chow-fed L-SACC1 mice with functional inactivation of Ceacam1, specifically in hepatocytes. The increase in CD4+ T cell pool was accompanied by elevation in hepatic mRNA content of IFNγ without changes in IL-4/IL-13 levels, suggesting increased production of CD4+ Th1, but not CD4+ Th2 cytokine in Cc1−/− livers. Elevated basal leptin level and its inducing effect on TNFα could contribute to the increase in CD4+ Th1 response. Given that Cc1−/− mice lack the anti-inflammatory effect of CEACAM1 in T+ and B+ cells, it is likely that deletion of Ceacam1 in lymphocytes contributed to the more robust inflammatory response to HF diet in mutant mice.

Consistent with insulin resistance being an independent predictor for fibrosis in NASH, chow-fed Cc1−/− null mice developed a low level of pericellular fibrosis. This could be attributed to elevated hepatic content of the profibrogenic factors, IL-6 and TGFβ. In addition to IL-6, leptin increases transcription of TNFα, which, together with IFNγ, reduces collagen synthesis. The combined effect of TNFα and IFNγ inflammatory cytokines could limit the profibrogenic effect of IL-6 and TGFβ in RD-fed null mice. HF feeding caused progressive fibrosis in parallel to preferentially inducing TNFα without changing IFNγ levels. TNFα triggers apoptosis, which in turn, leads to fibrosis and inflammation. Thus, it is possible that further induction in TNFα by HF diet activated caspase 3 to cause apoptosis and subsequently, promote fibrosis more preferentially in the null mouse. The increase in serum leptin levels could exacerbate the fibrogenic effect of TNFα.

In contrast to the null mouse, fat feeding elevated hepatic TGFβ, but not IL-6 mRNA content in Cc1+/+ wild-type mice. It also failed to produce NASH-like fibrogenic changes in these mice. IL-6 could be secreted basally from macrophages, but also from B cells as part of the adaptive immune response. Given that IL-6 release from B cells induces differentiation of hepatic stellate cells to myofibroblasts to mediate hepatic fibrosis in response to CCl4 in mice, independently of T cell or antibody stimulation, it is possible that changes in hepatic IL-6 levels contributed to the differential development of hepatic fibrosis in Cc1−/−, but not wild-type mice. This is in concordance with the positive correlation between the severity of the disease in NASH patients and hepatic IL-6 levels.

Our data emphasize that loss of CEACAM1 causes insulin resistance, hepatic steatosis and visceral obesity, with a subsequent increase in leptin production and release from white adipose tissue. This, in turn, promotes production of IL-6 and TNFα, which in addition to other adipokines, triggers a proinflammatory state. In the absence of CEACAM1, sustained HF feeding exacerbates the inflammatory response and elevates hepatic TNFα content and its proapoptotic and fibrogenic effect. This model illustrates that null mutation of Ceacam1 integrates metabolic, apoptotic, inflammatory, and fibrogenic signals leading to progressive NAFLD. Given that murine models rarely develop spontaneous fibrosis, the Cc1−/− mouse provides a unique tool to investigate the effect of environmental factors on genetic predisposition to NAFLD progression and sheds light on the pathogenesis of NASH. The significance of this finding to human disease is highlighted by the strong conservation of CEACAM1 func-
