Antibiotic prescribing practices by dentists: a review

Abstract: Antibiotics are prescribed by dentists for treatment as well as prevention of infection. Indications for the use of systemic antibiotics in dentistry are limited, since most dental and periodontal diseases are best managed by operative intervention and oral hygiene measures. However, the literature provides evidence of inadequate prescribing practices by dentists, due to a number of factors ranging from inadequate knowledge to social factors. Here we review studies that investigated the pattern of antibiotic use by dentists worldwide. The main defects in the knowledge of antibiotic prescribing are outlined. The main conclusion is that, unfortunately, the prescribing practices of dentists are inadequate and this is manifested by over-prescribing. Recommendations to improve antibiotic prescribing practices are presented in an attempt to curb the increasing incidence of antibiotic resistance and other side effects of antibiotic abuse.

Keywords: over-prescribing, antimicrobial resistance, recommended practice, penicillin

Introduction

Dentists prescribe medications for the management of a number of oral conditions, mainly orofacial infections. Since most human orofacial infections originate from odontogenic infections, the prescribing of antibiotics by dental practitioners has become an important aspect of dental practice. For this reason, antibiotics account for the vast majority of medicines prescribed by dentists. Dentists prescribe between 7% and 11% of all common antibiotics (beta-lactams, macrolides, tetracyclines, clindamycin, metronidazole). In the UK, for instance, dentists accounted for 7% of all community prescriptions of antimicrobials. On the other hand, the National Center for Disease Control and Prevention estimate that approximately one-third of all outpatient antibiotic prescriptions are unnecessary.

Antibiotic prescribing may be associated with unfavorable side effects ranging from gastrointestinal disturbances to fatal anaphylactic shock and development of resistance. The increasing resistance problems of recent years are probably related to over- or mis-use of broad-spectrum agents such as cephalosporins and fluoroquinolones. We have now entered an era where some bacterial species are resistant to the full range of antibiotics presently available, with the methicillin-resistant Staphylococcus aureus being the most widely known example of extensive resistance.

These serious complications associated with antibiotics use have encouraged studies investigating antibiotic prescribing practices of dentists.

The PubMed database was searched in February 2010, and search criteria included: antibiotic, dentist, and prescribing. Searches were limited to human studies published...
in English. Over 400 references were retrieved; 33 of them investigated antibiotic prescribing by dentists. These references were reviewed to evaluate the therapeutic and prophylactic antibiotic prescribing practices of dentists with a focus on indications of antibiotics, type of antibiotic prescribed, and the duration of prescription.

**Therapeutic antibiotic prescribing by dentists**

Most oral diseases presented to the dentist are primarily inflammatory conditions that are associated with pain. These inflammatory conditions and their associated clinical features are shown in Table 1. A considerable percentage of dental pain originates from acute and chronic infections of pulpal origin, which necessitates operative intervention, rather than antibiotics. Non-indicated clinical cases for antibiotic use include acute periapical infection, dry socket, and pulpitis. Chronic inflammatory periodontal conditions are also not indicated for antibiotics; systemic antimicrobials should only be used in acute periodontal conditions where drainage or debridement is impossible, where there is local spread of the infection or where systemic upset has occurred.

Data reported from different countries indicate differences in dentists’ knowledge of clinical situations indicated for antibiotics. Almost half or more of the dentists investigated in England, Kuwait, and Turkey would prescribe for dry socket. Another non-indicated condition is localized swelling, which was also among the conditions for which antibiotics were prescribed in Norway, South Australia, Kuwait, and England. On the other hand, the figures for England show that admissions for ‘drainage of an abscess related to tooth’ has doubled from just under 800 in 1998 to almost 1600 in 2006.

More common dental infections present in the form of pulpitis and periapical periodontitis, which require only operative measures like fillings, root canal therapy, or extraction if the tooth is not restorable. Unfortunately, dentists still prescribe antibiotics for this condition. A distressing finding was that a number of dentists prescribe antibiotics for viral infections like herpes simplex virus-1 infections.

Clinical situations that require antibiotic therapy on empirical basis are limited, and they include oral infection accompanied by elevated body temperature and evidence of systemic spread like lymphadenopathy and trismus. Facial cellulitis that may or may not be associated with dysphagia, is a serious disease that should be treated by antibiotics promptly because of the possibility of infection spread via lymph and blood circulation, with development of septicemia.

There are also a limited number of localized oral lesions that are indicated for antibiotic use and these include periodontal abscess, acute necrotizing ulcerative gingivitis, and pericoronitis.

Another aspect of antibiotic over-prescribing is prescribing based on non-clinical factors. Patient’s expectation of

an antibiotic prescription, convenience, and demand necessitated by the social background of the patients are considered unscientific reasons for antibiotic prescription. Whereas English and Scottish dentists would not prescribe for non-clinical factors,1 dentists in the Eastern Mediterranean region have shown a tendency to prescribe on a patient’s demand or socially, especially when short of time.15,17

The most commonly used antibiotic in dental practice, penicillins in general, were found to be the most commonly prescribed antibiotics by dentists,16,17,20 the most popular one being amoxicillin8,9,16,18,21,22 followed by penicillin V11,12,23 metronidazole,8,9 and amoxicillin and clavulanate.28

Penicillin is still the gold standard in treating dental infections.6 Among the group of penicillins, penicillin V,9 amoxicillin,29 and amoxicillin and clavulanate30 have been advocated for the treatment of odontogenic infections. Kuriyama et al found no difference in clinical outcome between penicillin V, amoxicillin, or amoxicillin and clavulanate.11

Frequency of prescribing is usually mentioned in the known resources for antibiotic prescribing,32 whereas duration of treatment recommended in therapeutic guidelines is most commonly based on expert opinion.33 A survey in Canada found that the average duration of antibiotic use prescribed by dentists is 6.92 days.13 Another survey in the USA found that endodontists prescribe antibiotic use for an average of 7.58 days.23 Recent studies on the attitudes of dentists in the Eastern Mediterranean region showed that dentists preferred to prescribe a lower dosage of an antibiotic over a longer period.15,18

In recent years, more attention has been given to short courses. Rubenstein explains that short-course antibiotic therapy requires that antibiotics have certain characteristics, such as: rapid onset of action, bactericidal activity, lack of propensity to induce resistant mutants, easy penetrability into tissues, activity against non-dividing bacteria, not being affected by adverse infection conditions (low pH, anaerobiosis, presence of pus, etc.), administration at an optimal dose, and optimal dosing regimen.33 A two-dose, 3-gm regimen of amoxicillin has been shown to be effective in certain situations.34 On the other hand, oral antibiotic use for 2 or 3 days has been advocated for the treatment of acute dentoalveolar infections, and in doses recommended by the British National Formulary (BNF).24 Indeed, in some studies, patients improved after 2 or 3 days of antibiotic therapy.31,35–37

In general, reducing the frequency of antibiotic intake (without compromising the dose) has yielded improved results: a twice-daily dosage of amoxicillin/clavulanate had several advantages over the three times-daily dosage, including increased convenience, improved compliance, and improved tolerability.38,39

Short courses are preferred to long courses particularly when treating children, since children’s compliance with conventional courses is poor.40 A false conception about the use of antibiotics is that antibiotics should be used for a certain number of days to ‘kill the resistant strains’ as the vast majority of strains acquire resistance via transposable elements that are preferentially transferred when antibiotics are used in sub-therapeutic doses or for long durations.41

In summary, antibiotics should be prescribed at the correct frequency, dose, and duration so that the minimal inhibitory concentration is exceeded, and so that side effects and the selection of resistant bacteria are prevented.9 Prolonged courses of antibiotics destroy the commensal flora.38 In addition, longer durations of up to 21 days may result in the selection of resistant strains and a reduction in the ability of the oral flora to resist the colonization by harmful micro-organisms that are not normal residents,42 leading to superimposed infections by multi-resistant bacteria and yeasts.15

**Prophylactic antibiotic prescribing**

Prophylactic antibiotics, taken prior to a number of dental procedures, have been advocated to reduce the likelihood of postoperative local complications, like infection, dry socket, or serious systemic complications like infective endocarditis. The evidence for antibiotics acting to prevent infection from surgical wounds in the mouth is poor to non-existent,14 indicating that preoperative parenteral antibiotic prophylaxis for routine third molar surgery in medically fit patients is unwarranted.41,44 It was also found that a single dose of metronidazole was ineffective in preventing the development of dry socket.45 For most dentoalveolar surgical procedures in fit, non-medically compromised patients, antibiotic prophylaxis is not required or recommended.46

In the case of bacterial endocarditis (IE), the absolute risk rate after dental treatment, even in at-risk patients, is considered very low.41 This is consistent with recent guidelines from the British Society for Antimicrobial Chemotherapy,47 and the American Heart Association,48 which recommend that only patients in the high risk category require cover. The basis for this recommendation is:

- There is no consistent association between having an intervention, dental or non-dental, and the development of IE.
- Regular tooth brushing almost certainly presents a greater risk of IE than a single dental procedure because of repetitive exposure to bacteremia with oral flora.
• The clinical effectiveness of antibiotic prophylaxis is not proven.
• Antibiotic prophylaxis against IE for dental procedures may lead to a greater number of deaths through fatal anaphylaxis than would a strategy of no antibiotic prophylaxis. Nor is antibiotic prophylaxis against IE cost effective.49

Most studies on prophylactic antibiotic use were carried out in developed countries,8,9,11,13,14 and the results generally indicated that dentists have a good knowledge of prescribing.

The few studies done in developing countries15,17 reported that abuse of prophylactic antibiotics was to prevent postoperative infection following surgical dental manipulations or to cover either a defect in aseptic clinical technique or improperly sterilized equipment; thus, a ‘just in case’ principle is practiced.17

Recommendations

Recommended treatment modalities for common inflammatory oral conditions are shown in Figure 1.

Drainage is the recommended treatment for periapical periodontitis and for localized dentoalveolar abscesses, with incisional drainage rather than via the root canal preferred.31

Empirical antibiotic therapy and drainage are recommended for more severe infections such as facial cellulitis, pericoronitis, lateral periodontal abscesses, and necrotizing ulcerative gingivitis.

The type of antibiotic chosen and its dosing regimen are dependent upon the severity of infection and the predominant type of causative bacteria.

According to the BNF, amoxicillin is recommended for dental infections in doses ranging from 250 mg to 500 mg, every 8 hours.50 The use of 3 g amoxicillin repeated after 8 hours is also mentioned, as a short course of oral therapy.50 Another antibiotic that is also recommended by the BNF is co-amoxiclav, which can be used in doses ranging from 375 mg to 625 mg every 8 hours.51 In patients allergic to penicillin, clindamycin can be used in doses ranging from 150 mg to 450 mg every 6 hours.52 Another option for penicillin-allergic patients (as recommended by the BNF) is metronidazole, which can be used in a dose of 200 mg every 8 hours for 3–7 days.53

For severe odontogenic infections, higher doses of a broad-spectrum antibiotic may be required. Lewis et al have shown that only 5% of the main isolates from dental abscesses are resistant to amoxicillin/clavulanic acid.54 A more recent study found that bacteria associated with endodontic infections are completely susceptible to amoxicillin/clavulanic acid.55 Furthermore, some researchers observed that amoxicillin/clavulanic acid and clindamycin are the only orally administered antimicrobials with adequate pharmacokinetic/pharmacodynamic properties to be effective against the most commonly isolated oral pathogens for the treatment of orofacial infections.39 When amoxicillin/clavulanic acid is used, a dosing regimen of 1 g twice daily provides a successful clinical outcome, better patient convenience and compliance, and less gastrointestinal upset owing to the minimizing of the clavulanic acid dose.39 As mentioned previously, patients can be seen after 2 or 3 days to determine whether treatment should be stopped or continued.

Patients who are allergic to penicillin should benefit from clindamycin; it is active against some oral anaerobes and facultative bacteria, and has the advantage of good bone penetration. However, increasing the dose may increase the possibility of serious side effects such as pseudomembranous colitis,56–58 Sweet’s syndrome,59 and neutropenia.60

Infections in which anaerobic bacteria are implicated (such as pericoronitis, periodontal abscesses and necrotizing ulcerative gingivitis) are better treated with metronidazole; the best dosage regimen in terms of pharmacodynamic/pharmacokinetic aspect is 250 mg every 8 hours.39

![Figure 1](https://www.dovepress.com/)

**Figure 1** Recommended treatment modalities for common inflammatory oral lesions.

**Notes:** A Operative intervention is needed, like filling, root canal treatment, local irrigation, incisional drainage, and oral hygiene measures. B Empirical antibiotic prescribing is needed as an initial treatment. Operative intervention(s) may be initiated on the same visit or later. Oral hygiene measures are mandatory.
Other inflammatory/painful oral conditions such as cracked tooth, dentine hypersensitivity, and bacterial sialadenitis are outside the scope of this review and their management is thoroughly explained in specialized references.

In addition to the proper dosing regimens and professionally responsible prescribing practices, the general public needs to be educated about the importance of restricting the use of antibiotics to only cases of severe infection. Patients have become accustomed to being given an antibiotic for a range of medical complaints. Unfortunately, patients presenting at dental surgeries also routinely expect an antibiotic for the treatment of ‘toothache’.

Dental patients not only pressure their dentist to get an antibiotic prescription, they also self-medicate. Self-medication with antibiotics was found to be alarmingly high in some developing countries.61–64 Also in Europe, self-prescription of antibiotics was reported, particularly in eastern and southern parts.65,66

In conclusion, prescribing practices of dentists can be improved by increasing awareness among dental practitioners of the recommended guidelines. Furthermore, the importance of initiating awareness programs among the general public should not be overlooked.
