Introduction: Smoking can cause vascular damage in the form of an inflammatory reaction characterized by endothelial activation. Endothelial activation forms a pathological adaptation pattern so that it can induce the atherogenesis process. Several markers, such as E-selectin, platelet-derived micro particles (PMPs) and hematopoietic stem cell (HSC) can identify the activation of endothelial in circulating blood. Therefore, the deviation of vascular adaptation due to smoking can be detected early through the feedback mechanism between E-selectin, PMPs, and HSC.

Purpose: This study aims to analyze the initial picture of the negative impact of smoking on vascular adaptation by measuring E-selectin, PMPs, and HSC in the peripheral blood circulation. Participant criteria and methods: Peripheral blood samples (5 mL) were taken from each participant, both the smoking group (n = 30) and the non-smoker group (n = 31) to obtain peripheral blood mononuclear cells (PBMNC). PBMNC was isolated using ficoll-based gradient centrifugation. The flow cytometry assay method used to measure the E-selectin, PMPs and hematopoietic stem cells.

Results: The mean of circulating E-selectin in smokers was higher than that of non-smokers. On the other hand, the average number of PMPs and HSCs in smokers was lower than non-smokers.

Conclusion: Smoking increases the risk of accelerated vascular block formation, as indicated by an increase in the amount of circulating E-selectin. The increase in E-selectin in the blood vessels mediates the increased adhesion of PMPs in the vascular area so that the number of circulating PMPs in smokers decreases. The decrease in circulating PMPs decreases the signal of vascular repair, which is characterized by a decline in the number of HSCs.

Keywords: endothelial injury, cardiovascular disease, atherosclerosis, peripheral blood mononuclear cells, smoker

Introduction

Smoking is one of the risky behaviours that can increase cardiovascular disease incidence. The long manifestation of smoking's adverse effect has to lead the perception among smokers that smoking does not harm health. Therefore, it is necessary to conduct studies that can detect the progression of cardiovascular disorders before the actual manifestation of the disease.

The endothelium has an essential role in regulating the coagulation system and vascular tone.¹ Changes in the structure and function of the endothelium are

a description of the response to vascular damage.²⁻⁴ Long-term smoking habits can interfere with endothelial function through the oxidative stress pathway.^{5,6} Nicotine is the most toxic component of cigarettes that can induce endothelial cell death.⁷⁻¹⁰ The increasing the number of circulating endothelial cells which is the final stage of the endothelial damage process is a sign for the endothelial cell death.¹¹ Endothelial damage can be preceded by endothelial activation, which is indicated by an increase in the amount of E-selectin.¹ E-Selectin or the so-called CD62 antigen-like family member E (CD62E) is an adhesion molecule that expressed when endothelial cells are activated by inflammation.¹² E-selectin is also present in activated platelets as a consequence of endothelial injury.¹³ E-Selectin mediates leucocyte adherence to injury areas and stimulates vascular inflammatory responses.¹³⁻¹⁵ E-Selectin is also considered a component involved in the self-renewal regulation of endothelial injury by Hematopoietic Stem Cell (HSC). Because of this dual role, E-selectin referred to as a regulator of cell-trafficking to areas of inflammation in humans.¹⁶ Soluble E-selectin can be identified in blood circulation by the ELISA method.^{15,17}

Endothelial damage causes loss of the primary vascular protective barrier so that circulating platelets adhere to collagen easily beneath the endothelial cells. Attachment of platelets to the area of endothelial injury causes platelets to become activated and produce higher amounts of Platelet-Derived Micro Particles (PMPs). The coagulation effect in the injured area by releasing thrombin, thereby increasing platelet adhesion to endothelial cells. At this stage thrombus formation in the injured area has begun.^{13,18,19}

The presence of PMPs in the blood circulation, both in pathological and physiological conditions, can be identified by identifying the surface marker with the CD41 marker.²⁰ A high circulating CD41 count can also be found in healthy individuals, not accompanied by endothelial/platelet activation. This condition is because megakaryocytes, as platelet precursors, also express CD41. So, the increase of CD41 levels in the circulation has two meanings, as a marker of platelet activation in pathological conditions and an increase in the number of megakaryocytes in physiological conditions.²⁰

Increased circulating CD41 will be detected by bone marrow (BM) as a signal that causes platelet activation to signal increased vascular repair needs. BM will produce high amounts of HSC when an extensive vascular

endothelial injury occurs. The presence of HSC in the circulation can be determined using CD133.²¹⁻²³ Circulating HSCs will undergo maturation to become Progenitor Endothelial Cells (EPC). The presence of PMPs plays a role in facilitating the planting of progenitor cells in endothelial areas that experience injury by increasing the attachment of EPC to fibrinogen.^{24,25} Endothelial damage is known to cause various forms of cellular responses. To maintain vascular homeostasis, as a form of vascular adaptation, can be identified by quantifying the circulating soluble marker as a marker of endothelial activation. This study does not seem to present anything new because the markers used have been established. Still, the study of vascular status in heavy smokers (> 10 cigarettes per day) for five years at the molecular level is a research that has not been widely carried out. This study aims to analyze the differences in the initial view of vascular adaptation in the smoker and non-smoker groups by measuring the amount of E-selectin, PMPs, and HSC in the peripheral blood circulation.

Materials and Methods

Research Design and Baseline Characteristic of Participants

This study used a cross-sectional design—recruitment of participants through filling in the willingness to take part in research via a google form. The google form link is distributed through social media for two weeks to get two groups of participants, namely the smokers and non-smokers. The Google form contains statements about participants' objectives, benefits, rights and obligations, as well as research procedures. Prospective participants are given the opportunity to learn the information, if the prospective participant has understood and agreed, they are asked to sign the informed consent electronically to follow the research.

The smoking group is consisted of people who had a smoking history of no more than five years at the time of the study. Meanwhile, the non-smoking group were people who had never smoked at all until the study ends. All participants in both the smoking and non-smoking groups had no history of cardiovascular and metabolic diseases such as diabetes mellitus, hypertension, infection, obesity, or cancer. The history of the disease was retrieved from the medical records of each participant. After two weeks of recruitment, there were 30 and 31 participants in the smoker and non-smoker groups, respectively.

Data Collection Procedure

Participants were confirmed not to be taking drugs before blood collection was carried out. Then vital signs (blood pressure, pulse, respiration, and body temperature) are examined. Blood collection is carried out in the Central Laboratory of Biomedical, Faculty of Medicine, Brawijaya University. Laboratory analysts did not know the smoking status of each participant during the process of collecting and analyzing the studied blood samples.

A total of 5 mL of peripheral blood which has been taken using the venous puncture procedure, then accommodated in an Ethylene Diamine Tetra Acetic (EDTA) tube. Blood was diluted with Axisshield's Lymphoperm in the same volume ratio in a 15 mL tube, then centrifuged for 30 minutes at 6000 rpm. Buffy coat, which is the result of PBMNC centrifugation, was taken with a clean pipette and accommodated in a new tube and added up to 10 mL of phosphate-buffered saline (PBS), centrifuged again for 10 min at 1200 rpm. The PBS washing procedure repeated for two times. The pellets are ready for staining.

Blood samples for measurement of E-selectin, CD41, and CD133 were obtained from the participants' peripheral blood from both smokers and non-smokers. None of the participants took antiplatelet drugs, anti-inflammatory drugs, or hypolipidemic agents. This screening excludes any conditions thought to influence the number of platelets microparticles as a parameter in the present study.

Flow Cytometry Analysis to Evaluate the Number of Circulating E-Selectin, PMPs and HSC

The detection of E-selectin was confirmed by staining Phycoerythrin (PE)-conjugated monoclonal anti-human CD62E Biolegend Cat No. 322606 on the obtained PBMNC. Platelet microparticles carried out by adding 5 µL of Peridinin Chlorophyll (PerCP)-conjugated anti-human von Willebrand Factor (vWF/CD41) from (Biolegend, UK; catalogue number: 303720). Meanwhile, measurement of HSC counts was confirmed by adding 5µL of anti-human CD133 Allophycocyanine (APC mouse-conjugated monoclonal antibody IgG2A clone # 170411 [FAB cat no. 11331A]. The flowcytometric analyzed using the BD FACSMelody™ Cell Sorter, and BD FACSCorus™ software simplifies sorting by using a streamlined workflow.

Data Analysis

All data were presented as mean value \pm standard deviation. The comparison between the two groups was analyzed by independent *t*-test. The statistical significance was assumed if the null hypothesis failed to reject based on *p*-value <0.05 .

Ethical Clearance

This research has been approved by the Research Ethics Committee of Brawijaya University with Reference Number 1206-KEP-UB-2019. All of the patients participate in this study provided informed consent that has been in accordance with the Declaration of Helsinki.

Results

Characteristics of smokers and non-smokers: height, weight, and pulse can be seen in Table 1. Each of these characteristics was not significantly different in the two groups. The analysis then continued by identifying the differences in the number of E-Selectin, PMPs, and HSC between the smokers and non-smokers (Figure 1 and Table 2).

Based on Figure 1, it is known that the mean number of E-selectin (measured by the CD62E marker) in the smoker group was higher than in the non-smoker group. Meanwhile, the mean number of PMPs (measured through

the CD41 marker) in the smoker group was lower than that of non-smokers. Meanwhile, the mean number of HSCs (measured using the CD133 marker) in the smoker group was lower in the non-smoker group. This condition indicates endothelial activation, which indicates vascular inflammation in the smoker group.

Table 2 shows that there is a significant difference between the mean E-selectin, PMPs, and HSC between the smoker and non-smoker groups. The mean of

circulating E-selectin in smokers was higher than that of non-smokers. On the other hand, the mean of PMPs and HSCs in smokers was lower than that of non-smokers.

Discussion

Atherosclerotic disease is associated with endothelium function changes that occur in some CVD risk groups such as smokers, diabetes, hypertension and hyperlipidemia. Various previous studies have suggested that smoking can cause damage endothelium function.²⁶ Damage to endothelium function due to long-term smoking habits is caused by increased production of free radicals that cause endothelial cell degradation resulting in decreased nitric oxide production.^{5,6} Some endothelial activation markers become the initial stage of vascular lesions' development.²⁷

The endothelial cells activate several Endothelial Microparticles (EMPs) released into circulation. The EMPs can be measure through surface makers such as E-selectin (CD62E), vascular cell adhesion molecules-1 (VCAM-1), and intercellular adhesion molecules-1 (ICAM-1).²⁸ The platelets will increase rapidly to respond

to endothelial injuries and secrete granule content into circulation called PMPs. Some platelet activation markers in circulation include P-selectin, CD40L, PF4, and GP IIb/IIIa (CD41)^{29,30} So, it is known that PMPs reflect platelet activation while EMPs markers become a representation of activation or endothelial dysfunction.³¹ The interaction of leukocytes and platelets in vascular endothelium induces inflammatory pathways, thrombosis and atherogenesis.^{32,33}

This study showed that the number of mononuclear cells expressing E-selectin in the blood edge of smokers was higher than the non-smoker group. The increase in E-selectin in smokers in this study can be attributed to the results of previous studies that mentioned that smoking habits cause dysfunction and endothelial activation.^{34,35} Detection of endothelial activation can be measured through circulating markers including one of them is by measuring soluble E-selectin.^{36–38} In this study, the circulating of cells that expressed E-selectin in the smoker group showed the same pattern as the soluble E-selectin measurement in another study describing the endothelial injury. The number of E-selectin circulated results from an increase in active proteolytic cleavage from the surface of endothelial cells that have been activated. Still, there is no explanation of E-selectin's biological activity and clearance.³⁹ In addition to showing endothelial activation, E-selectin's increase may provide an overview of vascular inflammatory alteration.¹⁷

Active smoking of one cigarette caused an immediate and significant increase in the numbers of circulating PMPs (CD41), CD45 and VE-cadherin (CD144).¹⁹ Platelet-derived MPs (PMPs) are also called platelet dust, are ultramicro-membranous vesicles that are 0.1–1.0 μm in diameter. PMPs are involved in various physiological functions, including endothelial repair.⁴⁰ To evaluate PMPs' role in the restoration of endothelial injury in the smoker group, quantification of circulating PMPs positive cell using flow cytometry in PBMNC smokers. This study's results are different from previous studies, the number of mononuclear cells that express markers of PMPs in smokers in this study tends to be lower compared to the non-smoker group. Some study mentioned that PMPs can improve adherence on the walls of the damaged vascular endothelium to stimulate the expression of adhesion receptors gene, such as epithelial membrane protein-1 and increased ICAM-1 expression, thereby mediating platelet recruitment and leukocytes to repair endothelial damage.^{4,41,42}

The decrease in the number of PMPs in smokers this time can be attributed to previous study statements regarding the possibility of increasing the number of PMPs in vascular endothelial dysfunction due to smoking habits. Platelets become the largest source of microparticle production in circulation. The number of PMPs in circulation can reach 70% to 90% of the total existing microparticles; this indicates the vital role of platelet function in shaping the homeostasis response of vascular systems.^{4,20}

According to the present study, smoking is a potentially reversible risk factor and seems to be causally associated with the hematopoietic system.^{43,44} The CD133, also known as prominin or AC133, is a highly conserved antigen expressed on hematopoietic stem cells.⁴⁵ This protein is absent on mature endothelial cells and monocytic cells and expressed in EPCs.^{21,46} Evaluation of the effects of smoking on circulating human hematopoietic stem cells using CD133 markers remains unclear. This study showed that the number of CD133 positive cell circulating in the group of smokers tended to be lower compared to the non-smoker group.

Tobacco components in cigarettes can directly affect various organs' functioning because they contain pro-inflammatory effects and cytotoxic effects. Inhalation of oxidant molecules in cigarettes causes various damage that can activate inflammatory responses (increased TNF- α , IL-1, IL-6 and IL-8).⁴⁷ When systemic inflammation occurs, HSCs located in bone marrow will undergo activation, expansion and proliferation.⁴⁸ The mobilization of bone marrow HSCs intended for tissue repair mechanisms that occur dynamically and are self-regulated by stem cells.

The mechanism of proliferation and differentiation of HSCs due to inflammatory stimulus is part of the acute immune response. The accumulation of exposure to inflammatory cytokines causes disruption and loss of function of HSCs.⁴⁹

Another study mentioned that pro-inflammatory cytokines are associated with decreased of stem cell factor (SCF), which are molecules that play a role in the mobilization of HSCs from bone marrow to circulation.^{50,51} So, it is likely that the mechanisms involved in decreasing the number of CD133 positive cells in smokers' circulation are related to previous studies that stated that the accumulation of oxidants in smokers leads to increased production of inflammatory cytokines that can inhibit the signalling in the bone marrow.

Research Limitations

Measurements of vascular endothelial damage and inflammatory cytokines in smokers not measured in this study may continue the next research process. The correlation of research parameters in this study is associated with several previous studies that discussed the effects of cigarettes on endothelial damage and the impact of cigarette components on inflammatory induction of oxidative stress related to bone marrow failure.

Conclusion

The increase in circulating E-selectin positive cells in smokers indicates activation and endothelial injury as an indicator of the early stages of vascular lesions' formation. Platelets respond to the presence of injury in the endothelium through an increase in the number of positive PMPs cells, followed by adhesion of positive PMPs cells in the endothelial area experiencing an injury. Thus, the number of positive PMPs cells in the circulation tends to decrease. The low number of PMPs in the circulation cannot stimulate the bone marrow to release HSCs into the circulation. When the number of PMPs in the circulation decreases, it cannot provide sufficient signalling for the bone marrow to release adequate circulating HSCs to mediate endothelial injury repair.

Vascular Health and Risk Management

Publish your work in this journal

Vascular Health and Risk Management is an international, peer-reviewed journal of therapeutics and risk management, focusing on concise rapid reporting of clinical studies on the processes involved in the maintenance of vascular health; the monitoring, prevention and treatment of vascular disease and its sequelae; and the involvement

of metabolic disorders, particularly diabetes. This journal is indexed on PubMed Central and MedLine. The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.
