Purpose: Patients with thyrotoxicosis show neuropsychological changes, and these may damage the quality of informed consent in clinical practice. Therefore, we examined patients' real-life preferences to assess whether change in risk preferences was dependent on thyroid function state.

Patients and Methods: The participants were 86 patients who were newly diagnosed with Graves' thyrotoxicosis between 1 January and 31 December 2018 (group A), and an additional 33 euthyroid patients diagnosed before 2018 (group B). In a survey conducted via a questionnaire based on the concept of behavioral economics, we sought to determine risk preferences, rationality of choices, and other relevant factors. An identical second survey was completed 6–12 months later by 36 patients in group A after their thyroid functions had been normalized by treatment, and by 11 euthyroid patients in group B. We performed paired analysis of the first and second surveys in 32 patients of group A and single regression analysis of a total of 140 surveys obtained from 119 patients by combining the first and second surveys of groups A and B with serum level of FT3 as an independent variable.

Results: The paired analysis indicated that there was no significant difference in any survey item. The single regression analysis revealed that willingness-to-pay (WTP) for preventive medicine and monthly average out-of-pocket (OOP) expenditure on medical care were both significantly positively associated with serum level of FT3. Patients in the hyperthyroid state tend to have high WTP for preventive medicine, which may be accelerated by the anchoring effect of OOP expenditure.

Conclusion: Almost all risk preferences of patients with Graves' disease are constant, rational, and reproducible in the hyperthyroid and euthyroid states. However, medical professionals should be aware that the willingness of patients with thyrotoxicosis to pay for medical costs may change after the normalization of thyroid function.

Keywords: informed consent, behavioral economics, out-of-pocket expenditure, anchoring effects

Introduction

It has been reported that patients with thyrotoxicosis show mental disturbances and behavioral changes that can include manic, depressive, or cognitive decrements.^{1,2} These patients sometimes have difficulty in concentrating and problems with memory or decision making.³⁻⁶ These mental symptoms usually disappear after reaching euthyroidism.^{7,8} Although the biological mechanism for these symptoms remains unknown, recent studies using functional neuroimaging techniques of positron emission tomography (PET) and single photon emission computed

tomography (SPECT) have revealed that excessive thyroid hormone induces abnormal metabolism in the limbic system and frontal cortex.^{9–11}

Informed consent for clinical treatment has evolved to become vitally important in modern medical practice. In general, informed consent requires patients to have the capacity to make relevant decisions in an autonomous and rational way,¹² in consideration of the specific risks and benefits. In patients who have mental disorders, special care should be taken to recognize possible disabilities in decision making when processing informed consent.¹³ Even without overt mental disturbance, however, it may be questionable whether patients with Graves' thyrotoxicosis are capable of making the reasonable decisions that the treating physicians would expect. If thyroid function state has a marked effect on patient preferences, then medical professionals should consider having a supporting decision-maker for the patient. Therefore, clarifying the risk preferences of patients with Graves' thyrotoxicosis seems critical for achieving high-quality informed consent.

The present study aimed to examine the risk preferences of patients with Graves' disease in terms of whether their risk preferences were constant or changed depending on thyroid function state. We have previously investigated risk preferences in a survey comprising real-life risk preference questions designed based on the concept of behavioral economics.^{14–16} In these studies, we demonstrated that irrational risk-seeking choices of patients with diabetes contributed to the progression of diabetic complications. We applied the same survey to patients with Graves' thyrotoxicosis and compared the results with those in the euthyroid state.

Patients and Methods

All 86 patients who were diagnosed with Graves' thyrotoxicosis between 1 January and 31 December 2018 (group A) were consecutively recruited to participate in a survey at the outpatient clinic of the Department of Diabetes, Endocrinology and Metabolism, Nippon Medical School Chiba Hokusoh Hospital, Chiba, Japan. The diagnosis of Graves' disease was based on hyperthyroxinemia, >1% of the Tc-99m pertechnetate thyroid uptake with bilateral diffuse scintigraphy and a positive thyroid stimulating hormone (TSH)-binding inhibitory immunoglobulin (TBII) or thyroid stimulating antibody (TSAb).¹⁷ Also recruited to participate in the survey were an additional 33 patients with Graves' disease who had been diagnosed prior to 2018 and had been in

euthyroid state for at least one year previously (group B). The exclusion criteria were consciousness disturbance (confusion, delirium, lethargy, stupor, and coma), overt psychiatric disorder (patients who required consulting with psychiatrists), mental retardation, dementia, inability to understand Japanese language, and those who declined the recruitment request. In addition to the take-home survey, explanation sheet, and consent form, each survey participant was given book coupons worth ¥500 (equivalent to \$5 USD) as token remuneration. The participants were asked to examine the explanation sheets and consent forms at home, complete the survey forms, and return them along with the signed informed consent form by postal mail. Of the 119 participants, 54 patients in group A and 11 patients in group B were recruited to participate in a second survey (flow chart in [Supplemental Figure S1](#)). The interval between the first and second surveys was 6–12 months, and all patients were in euthyroid state with methimazole, propylthiouracil ($n = 3$), or iodine (iodine only, $n = 3$; methimazole with iodine, $n = 2$) at the time of the second survey. The duration in euthyroid state in group A patients at the second survey was 112 ± 91 days (mean \pm SD). We used the same questionnaire for both surveys, as described previously,^{14–16} as a modified version of the Japan Household Survey on Consumer Preference and Satisfaction by the Institute of Social and Economic Research, Osaka University, Osaka, Japan (https://www.iser.osaka-u.ac.jp/survey_data/top_eng.html). The reliability and validity of the questionnaire have been established in the general population,¹⁸ including those with obesity¹⁹ and smokers.²⁰ The survey items sought to determine patients' risk preferences as well as relevant factors such as personal socioeconomic status, mind and mood, and propensity ([Supplemental Table S1](#), the Japanese version is shown in [Supplemental Figure S2](#)). We examined rationality in answers to hypothetical lottery and insurance policy questions (Q12 and Q13). Irrational answers were defined as violations of two axioms of the expected utility theory: completeness and transitivity, as described in our previous report.¹⁶ Serum levels of free thyroxine (FT4), free triiodothyronine (FT3), and thyrotropin (TSH) were determined at the time of survey recruitment by micro-particle enzyme immunoassay using an automated Abbott AxSYM system (Abbott, Tokyo, Japan). TBII and TSAb were measured by the DYNOfest TRAb Human kit "Yamasa" and the TSAb kit YAMASA EIA (Yamasa, Chiba, Japan). This study was conducted in accordance with the principles of the Declaration of Helsinki. The

study protocol, including the consent form with confidentiality clause, was approved by the Internal Review Board of the Ethics Committee of Nippon Medical School.

Statistical Analysis

Statistical analyses were performed using JMP[®] 13 (SAS Institute Japan, Tokyo, Japan). Paired analysis of differences between the results of the first and the second surveys were assessed with Student's paired *t*-test for continuous variables and McNemar–Bowker test for nominal scales. Using serum level of FT3 as an independent variable, single regression analysis was performed for the answers to Q1–Q5 and Q8–13 as dependent variables in which all answers were treated as continuous variables. Single logistic regression analysis was performed for the answers to Q6 and Q7 (procrastination) and Q12 and Q13 (rationality), with serum level of FT3 as an independent variable. In multiple regression analysis, variance inflation factor was used to detect multicollinearity. Statistical significance was set at $p < 0.05$.

Results

Table 1 lists the participants' characteristics. The first survey was completed by 65 patients in group A (76%) and 28 patients in group B (85%), and the second survey was completed by 36 patients in group A (67%), after their thyroid functions had been normalized by treatment, and 11 patients in group B (100%). Table 2 shows paired analysis of differences between the first and the second survey in patients in group A who were hyperthyroid at the first survey and euthyroid at the second survey. A total of 32 paired samples were obtained and analyzed with paired

t-tests for continuous variables and McNemar–Bowker tests for nominal scales. The paired test found no significant difference in responses to all survey items between the first and the second surveys.

Due to the diverse severities of thyrotoxicosis, we considered that dichotomization as hyperthyroid or euthyroid could risk loss of critical information and analytic power. Therefore, we analyzed the data using serum level of FT3 as a marker of thyroid function. Table 3 shows the single regression analysis of each survey item, using serum level of FT3 as an independent variable. A total of 140 surveys (combined first and second surveys of groups A and B) were analyzed, obtained from 119 patients. There was no association of the answers to risk preference items (Q1, Q2, Q10–13) with serum level of FT3. In addition, FT3 level did not influence survey items related to mind and mood: feeling rushed (Q3), sleep deprivation (Q4, Q5), estimated propensity to procrastinate (Q6, Q7), accept medical uncertainty (Q8), and make rational choices (Q12, Q13). In the items regarding preferences, willingness-to-pay (WTP) for a medicine that could reduce cardiovascular disease (CVD) risk (WTPcvr) (Q11) was the only factor significantly associated with serum level of FT3 ($p = 0.0052$). Figure 1 shows the linear fit of WTPcvr prices according to FT3 level ($R^2 = 0.058$). WTPcvr increased as FT3 level increased; however, among the relevant factors, out-of-pocket (OOP) monthly expenditure on medical care (OOPmed) (Q9) was also positively associated with FT3 level (Figure 2) ($R^2 = 0.0508$, $p = 0.0079$). OOPmed was also associated with WTPcvr (Figure 3) ($R^2 = 0.0840$, $p = 0.0008$). The same results were obtained when we

Notes: A total of 32 paired samples were analyzed. Data are presented as the number, %, or mean ± standard deviation. Paired t-tests were performed for continuous variables. ^aFor nominal scales, McNemar–Bowker tests were applied using chi-square test. ^bReference range. ^cOrdinal scales were treated as continuous variables. ^dTSH < 0.001 (μIU/mL) was calculated as zero.

Abbreviations: OOPmed, out-of-pocket average monthly expenditure on medical care; CVD, cardiovascular disease; WTPcvr, willingness-to-pay for a medicine that could reduce CVD risk.

analyzed data using serum levels of FT4 as a marker of thyroid function ([Supplemental Figures S3 and S4](#)).

To clarify the relationship between average OOPmed, WTPcvr, and serum level of FT3, we performed multiple regression analysis using WTPcvr as a dependent variable ([Table 4](#)). In this analysis, we included subjective risk estimation for CVD (Q10) and economic status (Q17) as independent variables because it seems reasonable to assume that these factors might affect WTPcvr price. The results indicate that FT3 level and OOPmed were independently associated with WTPcvr. Subjective risk estimation (Q10) and economic status (Q17) were not significantly associated with

WTPcvr. Multiple regression that allowed for correlation between the same individuals revealed the robust result of a statistically significant positive correlation between FT3 level and WTPcvr. No correlation between FT3 level and OOPmed was observed under this assumption.

Discussion

Patients' decision making in the process of informed consent is complicated by various factors, including mood state and personality traits.^{12,21} Although it has been previously suggested that patients with thyrotoxicosis showed impaired decision making,⁶ it is unclear whether their impaired

Notes: A total of 140 surveys (combined first and second surveys of groups A and B) obtained from 119 patients were analyzed. ^aSurvey return rate was analyzed as the serum FT3 levels obtained at recruitment. ^bFor the nominal scales, logistic regression analysis was performed with chi-square test. ^cOrdinal scales were treated as continuous variables.

Abbreviations: OOPmed, out-of-pocket average monthly expenditure on medical care; CVD, cardiovascular disease; WTPcvr, willingness-to-pay for a medicine that could reduce CVD risk.

decision making has a serious impact on the quality of informed consent in clinical practice. The design of the survey questionnaire used in the present study (Table S1)¹⁴⁻¹⁶ was based on the theory of behavioral economics, which has emerged as a new concept for clarifying irrational human behavior.²² Some of the survey items were adopted from an existing survey on consumer preference (Japan Household Survey on Consumer Preferences and Satisfaction^{19,20}). It is more suitable to examine patients' preferences in real life, which are relevant to informed consent, than to use those estimated by instrumental assessment. The present results demonstrated that general risk preferences, those of mind and mood (estimated by the survey items feeling rushed and sleep deprivation), and

propensity estimated for the items procrastination, acceptance of medical uncertainty, and rationality of choices in patients with Graves' disease in thyrotoxicosis were not significantly different from those in the euthyroid state, and were not associated with serum level of FT3. Regarding the paired analysis, the second survey was completed within one year after the first survey. This time interval might be too short for any difference to be detected, because it has been reported that some patients who achieve euthyroid function after treatment might still have neuropsychological problems.^{8,23} However, in terms of the quality of informed consent it is important that patients' decisions would not fluctuate over such a short period. Our results suggest that as long as their mental status is not seriously impaired,

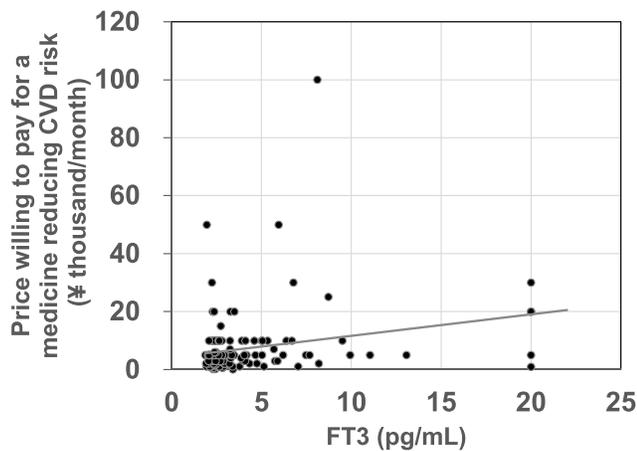

Figure 1 Linear fit of prices willing to pay for reducing CVD risk (Q11) according to serum level of FT3. Of the 140 returned survey forms from a cumulative total of 184 surveys given to 119 patients, 7 surveys in 6 patients did not have answers for Q11. A total of 133 answers in 113 patients were analyzed. Price willing to pay (¥/month) = $4219 + 741 \times \text{FT3 (pg/mL)}$, $R^2 = 0.0580$. Analysis of variance; degree of freedom = 1, sum of square = 1,000,897,112, F Ratio = 8.06, $p = 0.0052$.

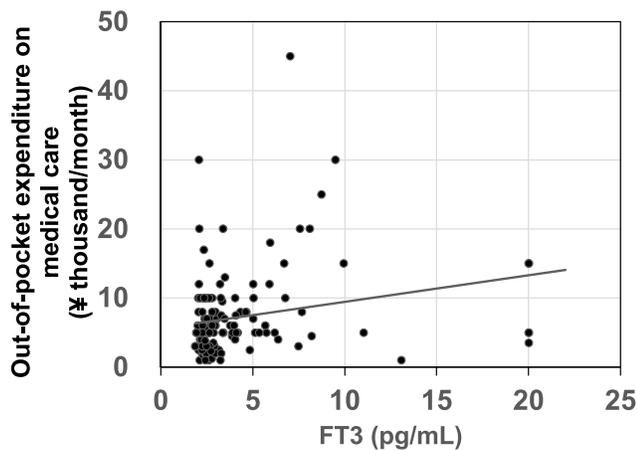

Figure 2 Linear fit of average out-of-pocket expenditure on medical care (Q9) according to serum level of FT3. Of the 140 returned survey forms from a cumulative total 184 surveys given to 119 patients, Q9 was not answered in two surveys. A total of 138 answers in 117 patients were analyzed. Out-of-pocket expenditure (¥/month) = $5599 + 385 \times \text{FT3 (pg/mL)}$, $R^2 = 0.0508$. Analysis of variance; degree of freedom = 1, sum of square = 273,587,993, F Ratio = 7.28, $p = 0.0079$.

informed consent obtained from patients with Graves' thyrotoxicosis is robust and independent of thyroid function state.

The questionnaire items WTP for a lottery ticket (Q12) and for an insurance policy (Q13) were used to determine rationality. Irrational responses were defined as violations of two axioms of the expected utility theory: completeness and transitivity.²⁴ These two axioms are familiar from consumer theory and are relevant to the process of informed consent. Gilboa speculated that the completeness axiom indicates that a certain choice has to be made and it rules out random

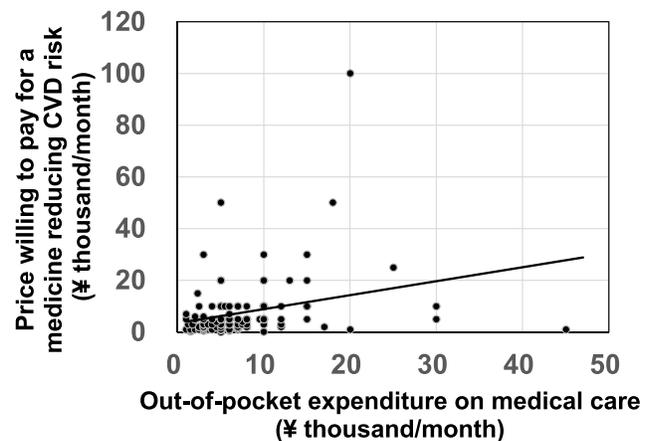

Figure 3 Linear fit of prices willing to pay for reducing CVD risk (Q11) according to average out-of-pocket expenditure on medical care (Q9). A total of 131 answers in 111 patients were analyzed. Price willing to pay (¥/month) = $3484 + 0.540 \times \text{out-of-pocket expenditure (¥/month)}$, $R^2 = 0.0840$. Analysis of variance; degree of freedom = 1, sum of square = 1,448,079,694, F Ratio = 11.84, $p = 0.0008$.

choices, and that transitivity (for any three outcomes A, B, and C, a preference for A over B and a preference for B over C implies a preference for A over C) is a mode of behavior that people would like to see themselves following.²⁵ In other words, following transitivity means that people understand what kind of behavior is expected of them. Patients are expected to make decisions following the logic that physicians recognize to be a matter of course, but this is not always the case. We recently demonstrated that the incidence of violation of the two axioms was higher in patients with diabetes and retinopathy than in those without retinopathy.¹⁶ The present results indicated that incidence of violations of the axioms (irrational responses in Q12 and Q13) is not associated with thyroid function state, thus proving that the rationality in patients' decision making was constant and deliberate.

The only exception among the preference items was for WTP_{cvr} when compared with serum level of FT3. WTP_{cvr} was positively associated with serum level of FT3. This result is robust with the assumption of the error term. This finding suggests that thyrotoxicosis may induce patients to be generous with their money. Yuan et al reported that patients with hyperthyroidism preferred a high immediate gain but greater loss over time, estimated by Iowa Gambling Test.⁶ Although we did not examine the myopic time preferences in the present study, bold gambling bets in patients with thyrotoxicosis may be compatible with generosity with their money and higher levels of WTP_{cvr}.

However, there is a possible contradiction to this interpretation. The result may be caused by "anchoring" of out-

Table 4 Multiple Regression Analysis of Factors Associated with Price Willingness-to-Pay for a Medicine Reducing CVD Risk (WTPc_{vr}) (Q11)

Independent Variable	Estimate	Standard Error	t Ratio	p value	VIF
Age (y)	24.6	68.0	0.360	0.718	1.02

Q17 Economic status ^a	-162	1141	-0.140	0.887	1.02

Notes: A total of 140 surveys obtained from 119 patients were analyzed. ^aOrdinal scale was treated as a continuous variable.

Abbreviations: OOPmed, out-of-pocket average monthly expenditure on medical care; CVD, cardiovascular disease; VIF, variance inflation factor.

of-pocket monthly expenditure on medical care (OOPmed). Tversky and Kahneman described that in this phenomenon, people make estimates by starting with an initial value that is then adjusted to yield the final answer.²⁶ Different starting points yield different estimates, which are biased toward the initial values. Because anchors that have informational relevance to the task can lead to the anchoring effect, it is plausible that OOPmed may be the initial value of the estimation of WTPc_{vr}. OOPmed is high during the first few months of medical care due to the number of tests that are required in a newly diagnosed patient, including blood tests for thyroid function and antibodies, nuclear thyroid scans, ultrasonography, and assessment of the cardiovascular system and other comorbidities. After the initiation of anti-thyroid medication, blood tests are then obtained every two to four weeks to monitor thyroid function and adverse effects until the euthyroid state is established. Additional assessments would be necessary in patients with comorbidities such as atrial fibrillation, heart failure, ophthalmopathy, glucose intolerance, or liver damage. Although this correlation is sensitive to the assumption of the error term, it may be possible that increased WTPc_{vr} was the result of anchoring effects of OOPmed.

In consideration of other aspects of WTP for preventive medicine, it has been reported that spending for health care is closely related to household income worldwide.^{27–29} In our previous study, we conducted exactly the same survey in patients with diabetes or stable endocrine or metabolic diseases.¹⁶ By way of comparison, we performed multiple regression analysis of the factors associated with WTPc_{vr} from the data of that study. The results, listed in [Supplemental Table S2](#),¹⁶ show that economic status was significantly associated with WTPc_{vr} in patients with chronic diseases, but OOPmed was not. There was no anchoring effect of OOPmed on WTPc_{vr} in patients with

chronic diseases, whereas economic status had a strong impact. It should be noted that the association of serum level of FT3 with WTPc_{vr} was statistically independent from OOPmed and economic status shown in [Table 4](#). Thyrotoxicosis increased patients' WTPc_{vr} independently of the anchoring effect. However, it has been suggested that this effect may be influenced by cognitive ability, personality traits, and mood,³⁰ and that hyperthyroidism affects decision making,⁶ executive function,⁴ and mood.² Therefore, thyrotoxicosis may additionally increase WTPc_{vr} by accelerating the anchoring effect of OOPmed.

One limitation of this study is that it included a small number of cases in a single facility in Japan. To avoid sampling bias, we recruited all patients who were newly diagnosed in 2018 and no patients were excluded by the recruitment criteria. At the time of recruitment, all of the patients agreed to participate, but the overall survey response rate was 76%. Accordingly, we collected no data from 24% of the eligible patients. However, the response rate was 73.9% in patients with thyrotoxicosis and 78.2% in euthyroid state, which was not significantly different. Therefore, it may be plausible that the response rate did not affect the overall conclusions. Demographic factors may be another limitation, and could have influenced responses to survey items regarding risk preferences. Risk preferences relevant to informed consent should be investigated for every country, ethnic group, and socioeconomic status by a method that does not depend on patients' willingness to volunteer. Further studies will be necessary in this regard. Despite these limitations, the present study supports the robustness of informed consent obtained from patients with Graves' thyrotoxicosis.

In conclusion, the risk preferences of patients with Graves' disease are constant and reproducible in both the hyperthyroid and euthyroid states. Informed consent during thyrotoxicosis is reliable as long as the patient's mental status is not seriously impaired. However, patients in

thyrotoxicosis may have higher levels of willingness to pay for medical costs than those in the euthyroid state, which may change after normalization of thyroid function. The findings of the present study suggest that investigations of disease-specific preference changes may be necessary for every disease.

Data Sharing Statement

The data that support the findings of this study are stored in the Department of Endocrinology, Diabetes and Metabolism, Graduate School of Medicine, Nippon Medical School, and are available from the corresponding author upon reasonable request.

Ethics Approval and Informed Consent

This study was conducted in accordance with the Declaration of Helsinki. The study was approved by the Internal Review Board of the Ethics Committee of Nippon Medical School Chiba Hokusoh Hospital (#415). The study participants provided written informed consent for the study contents, purposes, protocols, data confidentiality and anonymity procedures, and publication. Freedom to discontinue the study at any stage was explained and agreed upon.

Acknowledgments

The authors would like to thank FORTE Science Communications for assistance with English language review.

Author Contributions

All authors made a significant contribution to the work reported, whether that is in the conception, study design, execution, acquisition of data, analysis and interpretation, or in all these areas; took part in drafting, revising or critically reviewing the article; gave final approval of the version to be published; have agreed on the journal to which the article has been submitted; and agree to be accountable for all aspects of the work.

Funding

This study was supported by a Grant-in-Aid for scientific research from the Japan Society for the Promotion of Science (KAKENHI) for Research Project #17K08936 (FY 2017–2019).

Disclosure

The authors report no conflicts of interest.

Patient Preference and Adherence

Dovepress

Publish your work in this journal

Patient Preference and Adherence is an international, peer-reviewed, open access journal that focusing on the growing importance of patient preference and adherence throughout the therapeutic continuum. Patient satisfaction, acceptability, quality of life, compliance, persistence and their role in developing new therapeutic modalities and compounds to optimize clinical outcomes for existing disease

states are major areas of interest for the journal. This journal has been accepted for indexing on PubMed Central. The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.
