*These authors contributed equally to this work

Objective: To investigate the efficiency and safety of callispheres beads loaded with donafenib (DCBs) for embolization in a VX2 liver tumor, as well as the improvement of tumor angiogenesis following embolization.

Methods: Forty New Zealand white rabbit VX2 liver tumors were treated with four different drugs via the hepatic artery: NS (normal saline), CB (blank callispheres beads), ACB (adriamycin-loaded callispheres beads) and DCB (DCBs). Hematoxylin-eosin staining was performed to assess tumor necrosis, while MRI was employed to detect the changes in tumor size. The safety was evaluated by the liver and kidney function parameters, and the immunofluorescence and immunohistochemical staining were performed to reflect the tumor hypoxia and tumor angiogenesis following embolization.

Results: The DCB group had the smallest tumor growth rate, but the tumor necrosis rate was the highest of the four groups. Compared to the CB and ACB groups, the DCB group did not aggravate the liver damage and had no influence on kidney function. The staining results showed that, although the tumor hypoxia deteriorated after DCBs embolization, the expression of VEGF (vascular endothelial growth factor) reduced, thus inhibiting tumor angiogenesis.

Conclusion: DCB administration via hepatic artery is an effective and safe treatment for a preclinical liver cancer model, with the unique benefit of suppressing tumor angiogenesis following embolization.

Keywords: hepatocellular carcinoma, donafenib, transcatheter arterial chemoembolization, tumor angiogenesis, efficacy, safety

Introduction

Transcatheter arterial chemoembolization (TACE) is currently the most commonly used treatment for unresectable hepatocellular carcinoma (HCC).^{1,2} However, the residual tumor after TACE can enhance tumor angiogenesis by upregulating hypoxia-inducible factor-1 α (HIF-1 α) and vascular endothelial growth factor (VEGF) expression,^{3,4} leading to tumor progression or recurrence.^{5–7} In recent years, several studies have revealed that the high expression of VEGF after TACE could be antagonized by VEGF antibodies or antiangiogenic drugs,^{8–10} but how and when to combine antiangiogenic drugs with TACE is still an open question.¹¹ Interestingly, in the clinical trials which have been published, one of the key distinctions between the successful TACTICS trial and the prior fail trials

was the time to apply sorafenib.^{12,13} In fact, there is already evidence that the most suitable regimen for administering sorafenib is before VEGF expression increases.¹⁴

In addition to directly suppressing the growth of tumor cells through downregulation of the Ras/Raf/Mek/Erk signaling pathway, sorafenib also exerts an anti-cancer effect by suppressing angiogenesis via inhibiting VEGF receptor (VEGFR-1, 2, 3) and platelet-derived growth factor receptor (PDGFR).¹⁵ Donafenib, a novel oral small-molecule multikinase inhibitor,¹⁶ was developed by substituting a trideuteriomethyl group for a methyl on a sorafenib molecule,¹⁷ potentially enhancing molecular stability for an improved pharmacokinetic profile.¹⁸ Donafenib was considered to work in a similar way to sorafenib in terms of anti-cancer activity.¹⁷ An open-label, randomized, parallel-controlled, multicenter Phase II–III trial (ZGDH3) conducted in China showed that, when compared to sorafenib, donafenib had a significantly longer median overall survival (12.1 vs 10.3 months, $P=0.0245$) and appeared to have improved tolerability.¹⁶ Based on this research, donafenib has been approved for first-line treatment of advanced HCC in China in June 2021.

In this study, we established donafenib-loaded callispheres beads (DCBs), in which donafenib could be sustained released in a VX2 liver tumor model. After embolization, we looked into the efficiency, safety and improvement of tumor angiogenesis.

Materials and Methods

Materials

Donafenib tosylate prodrug (Zelgen Medicine Co. Ltd., Jiangsu, China) was dissolved in a mixture of 25.0% polyethylene glycol (PEG400, Sinopharm Chemical Reagent Beijing, China), 25.0% ethyl alcohol (Sinopharm Chemical Reagent Beijing, China) and 50.0% distilled water to obtain 5 mg/mL stock solution. Callispheres beads (CB) samples with 100–300 μm diameter range (Hengrui Medicine Co. Ltd., Jiangsu, China) were used for the study.

DCBs Characterizations

Donafenib has a similar chemical formula to sorafenib,¹⁸ and both carry a positive charge (NH^+) (Figure 1A). Composed of polyvinyl alcohol hybrid hydrogel linked to sulfonate group, CBs are net-like spheres carrying negative

Figure 1 (A) Chemical formula of sorafenib and donafenib; (B) loading profiles of 100–300 μm CBs with a maximal loading of 20 mg donafenib/g beads; (C) percentage curve of donafenib release.

charge,^{19,20} allowing drugs charged positively for interaction. The DCBs characterizations were explored as described in the previous literature.^{20,21} Specifically, the donafenib concentration was detected by a multimode plate reader (BioTek Epoch, USA) at 305 nm. The loading and releasing efficiency were indirectly calculated by the donafenib concentration of the supernatants, which were obtained from the mixture system at different times. All experiments were performed in triplicate.

The Loading Efficiency

100–300 μm CBs (1 g) and the stock solution containing 20 mg of donafenib were kept for 120 minutes in a shaker at room temperature. At 5 min, 10 min, 20 min, 30 min, 60 min and 120 min, an equal amount of supernatant was collected from mixtures.

The Releasing Efficiency

The DCBs were suspended in 10 mL of normal saline containing 1% Tween 80 (Solarbio Technology Co. Ltd., Beijing, China) and incubated at 37 °C on a programmable incubator shaker (SPH-1038, Shiping Experimental Equipment Co. Ltd., Shanghai, China) at 100 rpm. At 30 min, 1 h, 2 h, 3 h, 6 h, 12 h, 18 h and 24 h, the aliquots were taken for analysis, and the same volume of blank medium was added.

Study Design and Animal Model

40 healthy New Zealand white rabbits (2.0–2.5 kg) were purchased from the Experimental Animal Center of Tongji Medical College of Huazhong University of Science and Technology. All experimental protocols were performed in accordance with the National Institutes of Health Guidelines and approved by the Ethics Committee of Tongji Medical College at Huazhong University of Science and Technology. The rabbits were maintained with free access to food and water.

The VX2 liver tumor models were established as described in the previous literature.²⁰ Briefly, the VX2 tumor tissue was cut and separated into cubes at the size of 1 mm³ under sterile conditions, and then these pieces were stored in saline. Next, a tumor piece was embedded into each rabbit's hepatic left lateral lobe after anesthetized and then blocked with gelatin sponge to prevent the tumor mass from falling out or liver bleeding. Finally, the wound was sutured after ensuring no bleeding or complications. All rabbits were given intramuscular injection of penicillin for 3 days after the implantation

of tumor piece. All animals were assigned randomly into four groups: NS group (n=10) was treated with 0.3 mL normal saline; CB group (n=10) was treated with 0.3 mL blank microsphere; ACB group (n=10) was treated with 0.3 mL callispheres beads loaded with adriamycin (Hanhui Pharmaceutical Co. Ltd., Shanghai, China); DCB group (n=10) was treated with 0.3 mL DCBs.

MRI Scan Acquisition

The liver tumor size was evaluated by magnetic resonance (MR, 3T, PHILIPS, Holland) on 14 days after modeling and 7 days after TACE. The scanning parameters used for conventional MR (T1WI and T2WI) imaging were TR 600/TE 8.0 ms and spin-echo in T1WI, TR 2725/TE 65 ms, and fast spin-echo in T2WI, 12 cm×12 cm FOV, 3 mm thickness layer, and 152×152 matrix.²² The long diameter (a) and short diameter (b) of the tumors were measured independently by two experienced radiologists. The tumor volume was calculated as $V = \frac{a \times b^2}{2}$, and the tumor growth rate was calculated as $V_1 / V_0 \times 100\%$ (V_1 presented the tumor volume at 1 w after TACE).

Transarterial Chemoembolization Procedure

After baseline MRI, the embolization procedures were performed immediately on digital subtraction arteriography (DSA, Siemens Medical Solutions, Munich, Germany). Under general anesthesia, the right femoral artery was exposed surgically, and a 4-F vascular sheath (Radiofocus Introducer II, Terumo Medical) was introduced in the exposed artery. After that, a 4-F Cobra catheter (Cook, Inc., Bloomington, IN) and a 2.4-F coaxial microcatheter system (Terumo, Tokyo, Japan) were used to select the celiac artery, hepatic artery and tumor-feeding artery successively for angiography.²³ Then, the drugs or embolic materials were slowly injected by hand under careful real-time fluoroscopy to prevent nontarget embolization.

Sample Collection

The blood samples were collected through the ear artery of rabbits on 1 d, 3 d and 7 d after TACE. Serum was collected after centrifugation and stored at –80 °C. The bioanalysis machine (Lei Du Life Science Co. Ltd., Chemray 800, Shenzhen, China) was used to analyze the liver and kidney function, including alanine transaminase

(ALT), aspartate transaminase (AST), creatinine (Cr) and blood urea nitrogen (BUN).

Histopathologic Staining

At 1 week after TACE, all rabbits were sacrificed immediately after MRI scanning, then the tumor tissues were removed and preserved in 4% formaldehyde for 24 hours before paraffin-embedded sections were made. For staining, the prepared paraffin sections were first deparaffinized and rehydrated. All samples were stained with hematoxylin and eosin (HE)²⁴ to assess tumor necrosis. The immunohistochemical (IHC) staining of proliferating cell nuclear antigen (PCNA) to display cell proliferation, HIF-1 α to compare the extent of tumor hypoxia, was performed.²⁵ In addition, the immunofluorescence (IF) of CD31 and VEGF was performed to show the microvessel density (MVD) and VEGF expression.²⁶

Statistical Analysis

All data were described as mean value $\pm$ standard deviation and processed by SPSS statistics version 24.0 (SPSS Inc., Chicago, USA) and GraphPad Prism 8.0 (La Jolla, USA) software. The statistical methods of one-way ANOVA and LSD test were used to analyze the groups. A *P* value < 0.05 indicated significant difference. The histopathologic staining results were analyzed by Image J software 1.8.0 (Media Cybernetics, Rockville, MD, USA). The animal sample size was calculated by PASS 15.0 based on the previous study.²⁷

Results

DCBs Characterizations

Donafenib loading efficiency peaked between 20 and 30 minutes, and the loading curve remained stable after 30 minutes (Figure 1B). The mean maximum loadability was 64.35%. The donafenib release percentage gradually increased within 12h and then kept stable (Figure 1C). The total drug release percentage reached 49.08% within 24 h.

Tumor Growth and Necrosis Rates

The masses were clearly visible on MRI (Figure 2A and B), with hypointensity on T1WI and hyperintensity on T2WI, and the TACE process of VX2 liver tumor was shown in Figure 2C and D. Compared to the tumor growth rate of the NS group (253.49 $\pm$ 67.11%), the tumor growth rates of the CB, ACB and DCB groups were 192.17 $\pm$ 63.01% (*P*=0.113), 193.27 $\pm$ 47.25% (*P*=0.110) and 105.80 $\pm$ 36.42%

(*P*=0.001), respectively (Figure 2E). The tumor growth rate of the DCB group was lower than that in the CB (*P*=0.031) and ACB (*P*=0.022) groups, while there was no statistical significance between the CB and ACB groups (*P*=0.976) (Figure 2E). The tumor necrosis rate was defined as: $\frac{nT}{nT+T} \times 100\%$ (Figure 3A–D). Compared with the tumor necrosis rate of the NS group (35.93 $\pm$ 12.71%), those in the embolism groups were 75.59 $\pm$ 23.05% (CB, *P*=0.004), 91.87 $\pm$ 4.92% (ACB, *P*<0.001), and 96.10 $\pm$ 3.15% (DCB, *P*<0.001), respectively (Figure 2F). Interestingly, there was no statistical difference between the CB, ACB and DCB groups in the tumor necrosis rate (Figure 2F), implying that the beads, rather than the medicines, were the primary cause of tumor necrosis.

IHC and IF Staining Results

The quantitative analysis of IHC and IF staining revealed that, compared to the NS group, the expression of the HIF-1 α in all the rest of the embolism groups significantly enhanced (Figure 4A and B), which suggested these groups suffered a worsened hypoxic tumor environment after embolization. Although there was no difference in the expression of HIF-1 α between the CB, ACB and DCB groups (Figure 4B), the VEGF expression of the DCB group was significantly lower than that of the CB and ACB group (Figure 5B and D). In addition, MVD in the DCB group was lower than that in the CB and ACB group (Figure 5A and C), as well as the expression of PCNA (Figure 4A and C). These shreds of evidence showed that the DCBs could inhibit the expression of VEGF, the formation of the new blood vessel and the tumor cell proliferation.

Changes in Liver and Kidney Function

As shown in Figure 6 and Table 1, except for the NS group, all the rest of the groups suffered a process of liver function damage and gradual recovery (Figure 6A and B), while the kidney function was not affected (Figure 6C and D). The ACB group appeared to have more severe liver damage than the other groups. The ALT level of ACB was higher than that in the CB group (334.42 $\pm$ 120.68 vs 161.19 $\pm$ 33.91, *P*=0.011) and DCB groups (334.42 $\pm$ 120.68 vs 163.30 $\pm$ 29.52, *P*=0.012) on 7 days after TACE (Figure 6A, Table 1). The AST level of the ACB group was higher than that in the CB group on 3 days (194.76 $\pm$ 104.18 vs 77.67 $\pm$ 20.69, *P*=0.032) and 7 days (146.17 $\pm$ 71.74 vs 43.58 $\pm$ 23.70, *P*=0.032) (Figure 6B, Table 1) after TACE. Furthermore, whereas the DCB group's AST level was greater one day after TACE than

Figure 2 (A) Axial T2WI showing the mass with hyperintensity (white arrow); (B) axial T1WI showing the mass with hypointense (black arrow); (C) arterial angiography of a VX2 liver tumor before embolization; (D) after embolization with DCBs, the tumor staining disappeared; (E) the tumor growth rates of different groups after TACE; (F) The tumor necrosis rates of different groups after TACE. * $P<0.05$; ** $P<0.01$; *** $P<0.001$.

the CB group (937.26 ± 61.02 vs 548.42 ± 232.71 , $P=0.045$), there was no statistical difference at 7 days ($P=0.072$) (Figure 6B, Table 1). These pieces of evidence indicated that the damage to liver function in the DCB group was similar to the CB group and somewhat better than the ACB group, and donafenib did not aggravate the liver damage.

Discussion

The basic principle of TACE was composed of the local ischemic necrosis caused by embolic material and the anti-cancer effects produced by chemotherapy.²⁸ Increased tumor hypoxia after TACE, on the other hand, promotes both tumor resistance and the risk of tumor angiogenesis.^{7,29,30} Angiogenesis is necessary for tumor

Figure 3 (A) Representative HE staining of the tumor after TACE. (B) Showing the necrosis of tumor tissue and liver tissue (100×); (C) showing the Callispheres beads (100×, black triangle); (D) showing three primary tissues (100×).

invasion and migration and is an essential characteristic of tumor development, especially for HCC, a blood-rich tumor.²⁷ In addition, the abnormal structure of tumor

neovascularization leads to the development of edema, interstitial hypertension and further aggravates hypoxia, forming a vicious cycle of the hypoxic tumor

Figure 5 (A and B) Representative pictures of tumor CD31 (green) and VEGF (red) immunofluorescence (400×); **(C and D)** quantitative analysis of the expression of CD31 and VEGF. * $P < 0.05$; ** $P < 0.01$; *** $P < 0.001$.

environment.^{31–33} Therefore, breaking this vicious circle after TACE is the key to inhibiting tumor blood vessel growth, thereby improving tumor recurrence or progression of HCC.

In this current study, we established a sustained-release system containing donafenib and explored the effects of DCBs on improving tumor angiogenesis. We discovered that DCBs can decrease the high expression of VEGF following embolization, which is important for tumor angiogenesis and tumor immunity escape.^{34,35} The data revealed that the DCB group had a higher rate of tumor necrosis, but tumor growth rate and MVD were lower, implying that donafenib prevented tumor growth via reducing tumor angiogenesis. We also noticed a decrease in tumor cell proliferation in the DCB group, which might be due to a decrease in VEGF or a direct pharmacological effect, but was ultimately linked to the effect of donafenib. The dose of donafenib applied in this study was about

2 mg per rabbit, a relatively small dose determined based on clinical trials and previous work^{16,20} and a suitable dose to improve the tumor microenvironment while avoiding liver damage.^{36,37}

Administration of DCBs through the hepatic artery has unique advantages. Several studies have proved that this method can increase the drug concentration of the tumor foci while reducing the concentration of the drug in the serum, potentially decreasing the occurrence of side effects.^{15,24,38} Despite the lack of clinical trials, replacing TACE-loaded chemotherapeutics with antivascular drugs (eg, sorafenib, apatinib, sunitinib) has become a hot research direction in terms of basic research.^{19,20,38–40} Lipiodol and drug-eluting beads (DEBs) are the most commonly used drug delivery methods in these studies. Compared with lipiodol, the drugs can remain in the tumor foci longer due to the sustained release profiles of DEBs.^{41,42} Furthermore, lipiodol loading targeted drugs

Figure 6 Biochemical tests of VX2 liver tumor-bearing rabbits after TACE; (A) ALT levels; (B) AST levels; (C) Cr values; (D) BUN values. * $P < 0.05$.

damaged liver function more severely than lipiodol alone,^{23,38,39} while targeted drugs loaded with DEBs will not aggravate liver damage,^{19,28} which agrees with our experimental results. This finding could be explained by the fact that DEBs are solid embolic materials,^{43,44} resulting in less ectopic embolism.

It was worth mentioning that adriamycin appeared to do nothing but worsen liver function, considering there was no statistical difference between the CB group and the ACB group on both the tumor growth and necrosis rate. Several studies have found that chemoembolization was not better than bland embolization, which suggests that the role of

chemotherapy drugs used in TACE is currently unclear and controversial.^{45–47} A previous animal experiment has shown that doxorubicin was linked with more tumor necrosis,⁴⁸ which contradicts the findings of this investigation. The possible reason is that the effect of microspheres has a greater effect on tumor necrosis in this experiment (Figure 2F), and adriamycin has no effect on necrotic tumor cells.

There are also conflicts between the results of fundamental experiments and clinical research. Although the chemotherapeutic drugs used in TACE have a definite toxic effect on HCC cells,⁴⁹ the clinical benefit is not very clear,⁴⁵ which could be due to chemotherapeutic drug penetration into the tumor being insufficient.⁵⁰ In this study, we compared the effectiveness and safety of DCBs and ACBs (conventional TACE) embolization in a preclinical cancer model and proved that replacing the chemotherapeutic drugs with antivascular drugs can achieve better treatment effect.^{19,39} More importantly, we observed a decrease in the expression of VEGF and MVD in the DCB group, both of which are related to the prognosis of patients.^{51,52}

There were several limitations in the study: firstly, the number of animals in each group was limited. Secondly, the rabbit VX2 liver tumor is a perfect model for transhepatic artery embolization but an imperfect surrogate for human HCC because it is an adenocarcinoma cell line rather than human HCC cell line. This study set out to load donafenib onto callispheres microspheres and we found that donafenib can be released slowly in this system. When the DCBs were applied to the pre-clinical VX2 liver tumor model via the hepatic artery, donafenib can alleviate tumor angiogenesis and reduce tumor cell proliferation by reducing the expression of VEGF but did not aggravate the damage to liver function.

To summarize, DCBs embolization via hepatic artery is an effective and safe treatment that improves the tumor angiogenesis after embolization of HCC.

Journal of Hepatocellular Carcinoma

Dovepress

Publish your work in this journal

The Journal of Hepatocellular Carcinoma is an international, peer-reviewed, open access journal that offers a platform for the dissemination and study of clinical, translational and basic research findings in this rapidly developing field. Development in areas including, but not limited to, epidemiology, vaccination, hepatitis therapy, pathology

and molecular tumor classification and prognostication are all considered for publication. The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.

Submit your manuscript here: <https://www.dovepress.com/journal-of-hepatocellular-carcinoma-journal>
