Purpose: Interest in developing methods appropriate for mapping increasing amounts of genome-wide molecular data are increasing rapidly. There is also an increasing need for methods that are able to efficiently simulate such data.

Patients and methods: In this article, we provide a graph-theory approach to find the necessary and sufficient conditions for the existence of a phylogeny matrix with \( k \) nonidentical haplotypes, \( n \) single nucleotide polymorphisms (SNPs), and a population size of \( m \) for which the minimum allele frequency of each SNP is between two specific numbers \( a \) and \( b \).

Results: We introduce an \( O(\max(n^2, nm)) \) algorithm for the random construction of such a phylogeny matrix. The running time of any algorithm for solving this problem would be \( \Omega(nm) \).

Conclusion: We have developed software, RAPPER, based on this algorithm, which is available at http://bioinf.cs.ipm.ir/softwares/RAPPER.

Keywords: perfect phylogeny, minimum allele frequency (MAF), tree, recursive algorithm

Introduction

With the widespread availability of molecular data, computational methods for gene mapping are being developed. Often, the statistical properties and the behavior of these methods need to be assessed and tested by simulation. By increasing the number of computational methods for gene mapping, there is an increasing need for tools that can simulate data for long genomic regions. One of the most popular models used to infer haplotypes from genotype data is perfect phylogeny.1–3 This model reconstructs haplotype sequences with the assumptions of infinite sites and no recombination. Given a set of genotypes, the goal is to find a set of haplotypes that fit a perfect phylogeny. The solution divides haplotypes into disjoint blocks that are all compatible with a perfect phylogeny tree. Each block can be seen as a region of genome with different evolutionary history. Simulation of genotype or haplotype data based on a coalescent model is central to estimation methods and testing new methodologies. Coalescent simulation can be used to understand the statistical properties of DNA sequences under different evolutionary scenarios and also evaluate and compare different methods for haplotype analysis. A number of simulation programs have been developed under this model and are currently being used.4–11 We suggest a haplotype simulation to produce haplotype data with predefined allele frequencies with coalescent property. By using the set of haplotypes that satisfy the coalescent property, we can simulate a long genomic region, which can be used as an approximation to the evolutionary process that produce the real data. This simulation constructs a random perfect phylogeny matrix (PPM) with \( k \)
nonidentical haplotypes, \( n \) single nucleotide polymorphisms (SNPs), and a population size of \( m \) in which the minimum allele frequency (MAF) of each SNP is between two pre-defined numbers. A simulated data set for generating a long DNA sequence can be constructed based on assumptions about recombination rate and distribution in an evolutionary model among these perfect phylogeny blocks. The phylogenetic tree is represented by a matrix \( A \) in which \( a_{ij} \) is the state of character \( j \) in sequence \( i \), and the \( i \)th row is the character vector of sequence \( i \). In this article, we assume that characters are binary and directed, ie, only 0→1 changes may occur on any path from the root to a leaf of the tree. For the output, the ancestral state of an allele is represented by zero. We suggest a haplotype simulation approach that produces haplotype data with prespecified allele frequencies that satisfy coalescent model, ie, it produces a phylogenetic tree in which branches model the changes through the time of evolution based on the model. By above discussions, finding a method to construct random PPM with \( k \) nonidentical haplotypes, \( n \) SNPs, and a population size of \( m \) in which the MAF of each SNP is between two specific numbers \( a \) and \( b \) will be very useful for data simulation (We consider MAF of each SNP is between two specific numbers). A simulated data set for generating a long allele frequency (MAF) of each SNP is between two predefined numbers. A simulated data set for generating a long allele frequency (MAF) of each SNP is between two predefined numbers. We suggest a haplotype simulation approach that produces haplotype data with prespecified allele frequencies that satisfy coalescent model, ie, it produces a phylogenetic tree in which branches model the changes through the time of evolution based on the model. By above discussions, finding a method to construct random PPM with \( k \) nonidentical haplotypes, \( n \) SNPs, and a population size of \( m \) in which the MAF of each SNP is between two specific numbers \( a \) and \( b \) will be very useful for data simulation (We consider MAF of each SNP is between two specific numbers)

1. \( B \) is a PPM
2. The number of 1’s in each column is between \( a \) and \( b \)
3. \( B \) has \( k \) nonidentical rows

**Example 1.** The following matrix \( B \) is a \((3,2,3)\)-PPM.

\[
B = \begin{bmatrix}
1 & 1 & 0 \\
1 & 1 & 0 \\
0 & 0 & 1 \\
0 & 0 & 1 \\
1 & 0 & 0 \\
\end{bmatrix}
\]

**Definition 2.** The matrix \( A_{kstan} \) is called \((m,a,b)\)-extendable if

1. \( A \) is a PPM
2. \( A \) has \( k \) nonidentical rows
3. There exists a matrix \( B_{m,a} \) that is a \((k,a,b)\)-PPM, and the rows of \( A \) and \( B \) are identical. (In this case, we say that \( A_{kstan} \) is extendable to \( B_{m,a} \))

**Example 2** \( A \) is \((5,2,3)\)-extendable to \( B \).

\[
A_{3x3} = \begin{bmatrix}
1 & 1 & 0 \\
1 & 0 & 0 \\
0 & 0 & 1 \\
\end{bmatrix} \rightarrow B_{5x5} = \begin{bmatrix}
1 & 1 & 0 \\
1 & 1 & 0 \\
0 & 0 & 1 \\
0 & 0 & 1 \\
1 & 0 & 0 \\
\end{bmatrix}
\]

It is obvious that there exists a \((k,a,b)\)-PPM matrix \( B_{m,a} \) if and only if there exists an \((m,a,b)\)-extendable matrix \( A_{kstan} \).

**Definition 3.** A matrix \( B \) is called good if it can be decomposed as follows:

1. The entries of its leftmost column are all 1’s.
2. There exist good matrices \( B_{ij} \) such that the rest (0 or more) of the columns of \( B \) form the block structure, as illustrated in Figure 1.

**Definition 4.** A matrix \( A \) is called canonical if it satisfies the second condition of the good matrix definition.

In the following definition, we assign a root to each good matrix.

---

### Preliminaries

To find some necessary and sufficient conditions for the existence of a PPM with \( m \) rows, \( k \) nonidentical rows, and \( n \) columns such that in every column, number of 1’s are between \( a \) and \( b \), we need some definitions. We consider the cases that \( k \geq 2 \).

**Definition 1.** Let \( a \) and \( b \) be 2 integers and assume \( a \leq b \). The matrix \( B_{m,a} \) is called a \((k,a,b)\)-PPM if

---

**Figure 1** Block structure of a good matrix.
Definition 5. In a good matrix $B$, we consider the leftmost all-one column as the root of the $B$.

Matrices and trees
Constructing a tree from a matrix
According to Theorem 8 of Pe’er et al., every PPM has an ordering of its rows and columns, which yields a canonical matrix.

Theorem (Pe’er et al.). Let $B$ be a binary matrix. The following are equivalent:
1. $B$ has a phylogenetic tree.
2. There exists an ordering of the rows and columns of $B$, which yields a canonical matrix.

Let $A_{kxn}$ be a PPM that consists of $B_1$, $B_2$, ..., $B_d$ good blocks and $c_i$ be the corresponding root of $B_i$. Following Gusfield, we construct a labeled tree $T_{(\delta)}$ by using the following steps (see Figure 2):

1. Add an all-one column to $A$ as the leftmost column. Index this column by 0.
2. Let vertex 0 be the parent of $c_i$ for all $1 \leq i \leq d$.
3. Construct a tree from canonical form of every $B_i$ in a recursive manner. (Note that $B_i$ is a good matrix and has an all-one column.)

The vertex set of $T_{(\delta)}$ is $\{0, 1, 2, \ldots, n\}$. Now, we label some vertices of $T_{(\delta)}$ as follows:

If the last 1 entry in row $r$ occurs in column $j$, then we label vertex $j$ of $T_{(\delta)}$ with $r$. Gusfield proved the following lemma.

Lemma 1. Every leaf of $T_{(\delta)}$ is labeled, and every vertex is labeled at most once.

Necessary and sufficient conditions for PPM
Let $A$ be a matrix and $O_u = \{r|a_{ru} = 1\}$. According to Estabrook et al and Meacham, $A$ is PPM if and only if for every two columns $u$ and $v$, $O_u \cap O_v = \emptyset$ or $O_u \subset O_v$ or $O_v \subset O_u$.

Lemma 2. Let $r$ be a row in $A$ and $v$ be a vertex in $T_{(\delta)}$ with label $r$; then $a_{ru} = 1$ if and only if $u$ is located in a path from root to $v$.

Proof. Let $u$ be located in a path from root to $v$. So $u$ is an ancestor of $v$. By the way that the tree was constructed from canonical form of matrix $A$, we have $O_v \subset O_u$. So, if $a_{ru} = 1$ then $a_{ru} = 1$.

Now, let $a_{ru} = 1$. Since $v$ is labeled by $r$, the last nonzero entry of $r$ occurs in $v$. So, for every child of $v$ such as $w$, we have $a_{rw} = 0$. Therefore, $a_{ru} = 1$ implies that $u$ is not a child of $v$. As $a_{ru} = a_{rv} = 1$, $O_u \cap O_v \neq \emptyset$. Thus, $O_u \subset O_v$ or $O_v \subset O_u$. Since $u$ is not a child of $v$, $O_u$ is not a subset of $O_v$. So, we have $O_v \subset O_u$, and $u$ is an ancestor of $v$. Therefore, $u$ is located in a path from root to $v$.

Constructing a matrix from the tree
Definition 6. A rooted tree $T$ is called a $(k,n)$-complete tree if it satisfies the following conditions:
1. $V(T) = \{0,1,2,\ldots,n\}$.
2. For every $1 \leq i \leq k$, there exists exactly 1 vertex with label $i$.
3. Every leaf is labeled.
4. Every vertex has at most 1 label.

From Lemma 1 and the way we construct $T_{(\delta)}$, we obtain that $T_{(\delta)}$ is $(k,n)$-complete tree where $A_{(\delta)}$ is a PPM. Now, for every $(k,n)$-complete tree $T$, we construct a PPM $A_T^{(\delta)}$ with nonidentical rows as follows:

Let $c$ be an arbitrary vertex of $T$ and $T_c$ be the subtree of $T$ with root $c$. We construct $A^T = [a_{ij}]$ by $a_{ij} = 1$ if and only if there exists a vertex in $T_c$ with label $i$. Gusfield (1991) showed that $A^T$ is a PPM. Let $r$ be a row of $A$, which is the
label of $u$ in $T$. Similar to Lemma 2, $a_{vw} = 1$ if and only if $w$ is located in a path from root to $u$. Since labels are different and there is a unique path between the root and the vertices of $T$, rows of $A$ are nonidentical.

It is obvious that $A^{(t)} = A$ and $T^{(x)} = T$. Therefore, there is a one-to-one correspondence between the set of all PPM with $k$ nonidentical rows and $n$ columns and the set of all $(k,n)$-complete tree.

Extended tree

Let $A_{km}^{(t)}$ be an $(m,a,b)$-extendable matrix, and let the $(k,a,b)$-PPM matrix $A_{km}$ be its extension and $T_{km}^{(a)}$ be its corresponding tree. Let $w$ be the repeating time function defined on the labeled vertices of $T_{km}^{(a)}$, as $w(v) = t$ if and only if $v$ is labeled by $r$ and row $r$ is repeated $t$ times in $B$. We call $(T_{km}^{(a)},w)$ the $(m,a,b)$-extended tree of $A$ and $w(v)$ the repeating label of $v$.

**Lemma 3.** The MAF of column $c$ in $B$ is the sum of the repeating labels of the vertices in $T_{c}$.

**Proof.** Let $a_{c} = 1$. Then, by Lemma 3.2, $c$ is located in a path from root to vertex $v$ with label $r$. So, $v$ is a vertex of $T_{c}$. Let $w(v) = t$. Corresponding to $t$ repetitions of $r$, we have $t$ ones in column $c$. Therefore, the MAF of column $c$ is equal to the sum of repeating labels in $T_{c}$.

**Example 3.** For matrices in Example 2, repeating labels and MAFs are shown in Figure 3. Let $A_{km}$ be an $(m,a,b)$-extendable matrix and $(T_{km}^{(a)},w)$ be the $(m,a,b)$-extended tree of $A$. Now, by the previous lemmas, we have the following observations.

**Observations:**

- $O_{1}$: Let $u$ be the ancestor of $v$ in $(T_{km}^{(a)},w)$, then the MAF of column $u$ is greater than or equal to the MAF of column $v$.

- $O_{2}$: Let $v$ be a leaf with label $r$ in $(T_{km}^{(a)},w)$. By proof of Lemma 3.1, column $v$ in $A_{km}$ has only $1$ nonzero entry in row $i$. Since the MAF of column $v$ should be at least $a$, $w(v) \geq a$.

- $O_{3}$: Let $T_{u}$ have $l$ leaves and $c$ labeled internal vertices. By using Lemma 4.1 and $O_{3}$, the MAF of column $u$ in $B$ is at least $al + c$.

- $O_{4}$: Let $T_{u}$ have $l$ leaves and $c$ labeled internal vertices. Since the MAF of each column in $B$ is at most $b$, $O_{4}$ implies that $l \leq b/a$.

- $O_{5}$: Let $x_{1}, x_{2}, \ldots, x_{b}$ be the children of root $r$ of $(T_{km}^{(a)},w)$. Then, using $O_{4}$ for each labeled vertex $x_{i}$, we have $w(x_{i}) \leq b$ if and only if $w(x_{i}) \leq b$ for every labeled vertex of $(T_{km}^{(a)},w)$.

In the following theorem, we show that we can always assume that the desired matrix has at least one all-zero row. By the MAF of vertex $v$ in $T_{km}^{(a)}$, we mean the MAF of column $v$ in $A^{(t)}$.

**Theorem 1.** There is an $(m,a,b)$-extendable matrix $A_{km}$ if and only if there is an $(m,a,b)$-extendable matrix $A_{km}^{*}$ that has a zero row.

**Proof.** It is obvious that root $r$ of $T_{km}^{(a)}$ is labeled when $A$ has a zero row.

Let $A$ has no zero rows and $r$ is not labeled. We consider two cases:

1. There exists an internal node $u$, which is labeled by $p$. In this case, we consider the labeled tree $T'$ by removing label $p$ of $u$ and giving $p$ to $r$.

2. Let only the leaves of $T_{km}^{(a)}$ be labeled. Consider vertex $x$ such that degree $x$ in $T_{km}^{(a)}$ is at least 2, and in $T_{km}^{(a)}$, every vertex of $T_{km}^{(a)} - x$ has at most 1 child (as $k \geq 2$ and there is no labeled internal node and $T_{km}^{(a)}$ has at least two leaves, there exists such $x$). Let $u$ and $v$ be two leaves of $T_{km}^{(a)}$ and $z$ be the ancestor of $v$ and the child of $x$. (If $v$ is a child of $x$ let $z = v$.) Since $u$ is a leaf of $T_{km}^{(a)}$, it has a label such as $p$. By removing edge $xz$ from $T_{km}^{(a)}$, labeling $p$ from $u$, adding edge $xz$, and giving $p$ to $r$, we obtain a new labeled tree $T'$ (Figure 4). In both cases, we define repeating time function $w'$ on the labeled vertices of $T'$ by

$$w'(v) = \begin{cases} w(v) & v \neq u \\ 0 & v = u \\ w(u) & v = r \end{cases}$$

![Figure 3](image-url)  Figure 3 Repeating labels and minimum allele frequency (MAF).

![Figure 4](image-url)  Figure 4 New labeled tree $T'$ obtained from $T$.  

For personal use only.

Dovepress
It is obvious that $T'$ is a $(k,n)$-complete tree, which has a zero row. Now, by using $O_\ell$, ..., $O_3$ and Lemma 3, we conclude that $A''$ is $(m,a,b)$-extendable.

**Necessary conditions**

In this section, we describe some necessary conditions for the existence of an $(m,a,b)$-tree. By applying Theorem 1, we find the conditions necessary for the existence of an $(m,a,b)$-tree in which the root has been labeled. First, we introduce some necessary conditions, and then in the next section, we will show that these conditions are also sufficient.

**Theorem 2.** Assume that $T$ is a $(k,n)$-complete tree and $(T,w)$ is an $(m,a,b)$-tree in which the root has been labeled. Let $r$ be the root of $T$, $\deg_r(r) = d$, and $T$ has $l$ leaves. Then

1. $l \leq k - 1$.
2. \[ \frac{k + (a - 1)l - 1}{b} \leq d \leq l. \]
3. $l(a - 1) + km \leq 1$.

**Proof.**

1. Since $r$ and the leaves of $T$ are labeled with nonidentical rows, 1 holds.
2. It is obvious that $d \leq l$. By $O_\ell$ for each leaf $v$, $w(v) \geq a$. Suppose $x_\ell,x_{\ell+1}, \ldots, x_d$ are the children of $r$, and $T_{x_\ell}$ contains $l$ leaves and $c_i$ internal labeled vertices. Then by $O_\ell$, we have

\[ l + c_i \leq b, \quad 1 \leq i \leq d. \]

Therefore

\[ \sum_{i=1}^{d} (al_i + c_i) \neq bd \]

\[ al + k - l - 1 \leq bd \]

So,

\[ \frac{k + (a - 1)l - 1}{b} \not\equiv d \]

3. By $O_\ell$, for each leaf $v$, we have $w(v) \geq a$, and for each labeled vertex $u$, we have $w(u) \geq 1$.

Then, the number of rows in a $(k,a,b)$-PPM matrix $B_{m,a,b}$, which is an extension of extended $A_\ell$, is at least

\[ al + (k - l). \]

We categorize the children of $r$, $x_\ell,x_{\ell+1}, \ldots, x_d$, into 3 groups:

- $A_1 = \{ x_\ell | x_\ell \not\in \alpha \delta \lambda = 1 \}$
- $A_2 = \{ x_\ell | x_\ell \not\in \alpha \delta \lambda \not= 1 \}$
- $A_3 = \{ x_\ell | x_\ell \not\in 0 \}$

Let $\alpha = |A_1|$ and $\beta = |A_2|$.

**Theorem 3.** Let $(T_w)$ be the same as in Theorem 2 and $B_{m,a,b}$ is its corresponding $(k,a,b)$-PPM. Then

1. $l \leq b/a$
2. $d + l - n \leq a$
3. Let $a/b$ (a be a divisor of $b$ and $a \neq b$); then the number of $x_i$ in which $T_{x_i}$ has $b/a$ leaves is less than or equal to $n - k + 1$.

**Proof.**

1. It results from the observation $O_\ell$.
2. Let $n_i$ be the number of vertices of $T_{x_i}$. Then, obviously

\[ n_i \leq \begin{cases} c_i + l, & c_i \geq 1 \\ l + 1, & c_i = 0 \text{ and } l_i \neq 1 \\ 1, & c_i = 0 \text{ and } l_i \neq 1 \end{cases} \]

So, we have

\[ n = \sum_{i=1}^{d} n_i \]

\[ = \sum c_i \geq 1 \| \sum c_i = 0, l_i \neq 1 \sum c_i = 0, l_i = 1 \]

\[ = \sum c_i + \sum l_i + \beta \]

Now, we find the upper and lower bounds.

- **Upper bound**

\[ n \geq \sum c_i + \sum l_i + \beta \]

\[ = k - l - 1 + l + \beta \]

\[ \Rightarrow \beta \leq n - k + 12 \]

- **Lower bound**

We have $|A_1 \cup A_2| = d - a$. Since the number of internal vertices of $T$ which have labels is $k - l - 1$,

\[ \beta \geq (d - a) - (k - l - 1) \]

\[ = d - \alpha + l - k + 1 \]

Now, we have

\[ d - \alpha - k - l - 1 \leq n - k + 1 \]

\[ d + l - n \leq \alpha \]

and part 2 is thus proved.

3. Suppose $a/b$ and $a \neq b$. Let $S = \{ x_i | l_i = b/a \}$. By observation $O_\ell$, for each $x_i \in S$, we have $c_i = 0$. So, $S \subseteq A_2$, and by inequality 1, we have $|S| \leq n - k + 1$.

**Sufficient conditions**

In the previous section, we obtained some necessary conditions for the existence of an $(m,a,b)$-extendable tree whose root has been labeled. In this section, we show that these
conditions are sufficient too. For this purpose, let $l_1, l_2, \ldots, l_d$ satisfy the conditions of Theorems 2 and 3. Then, we introduce an algorithm for constructing the rooted $(m,a,b)$-extendable tree $T$ with root $r$; $x_1, \ldots, x_d$ are the children of $r$ and $T_r$ has $l$ leaves. First, we determine the number of labeled internal nodes in each $T_r$.

**Determination of $c_i$**

We categorize the children of $r$ into three groups:

1. $G_1$: Children with $l = 1$. By Theorem 3, part 2, we have $|G_1| \geq d + l - n$.
2. $G_2$: Children with $l = b/a$ and $l \neq 1$.
3. $G_3$: Children with $l = b/a$ for $b \neq a$. By Theorem 3, part 3, we have $|G_3| \geq n - k + 1$.

According to $G_1, G_2,$ and $G_3$, we determine $c_i$ as follows:

1. For each $x_i \in G_1$ and $d + l - n$ elements of $G_1$, we set $c_i = 0$.
2. Let $|G_2| \leq k - l + 1$. Then, for each $x_i \in G_2$, we assign $c_i = 1$. Now, we distribute the value $k - l + 1 - |G_2|$ among the members of $G_2$ and those of $G_1$ for which $c_i \neq 0$ or $c_i$ is not determined in step 1. Now, suppose $|G_2| \geq k - l + 1$. Let $F$ be a subset of $G_2$ of size $k - l + 1$. For each $x_i \in F$, set $c_i = 1$. For all the remaining vertices such as $x_j$ which is not considered in the above steps, we assign $c_j = 0$. By this procedure, part 2 of the Theorem 3, $(|A| \geq d + l - n)$ holds.

**Algorithm for determination of $c_i$**

1. Categorize $d$ children of the root
2. for $i = 1$ to $d$
3. if $l = 1$ then put this child in $G_1$
4. if $l \neq b/a$ and $l \neq 1$ then put this child in $G_2$
5. if $l = b/a$ and $b \neq a$ then put this child in $G_3$
6. determine $c_i$ (related to each $x_i$) according to $G$
7. if $x_i \in G_3$ or $d + l - n \in G_1$
8. $c_i = 0$
9. else if $|G_2| \leq k - l + 1$
10. if $x_i \in G_2$ then
11. $c_i = 1$
12. Distribute $k - l + 1 - |G_2|$ among members of $G_2$ and those of $G_1$ for which $c_i \neq 0$
13. else if $|G_2| > k - l + 1$
14. $F \leftarrow$ (subset of $G_2$ of size $k - l + 1$)
15. if $x_i \in F$ then $c_i = 1$
16. else $c_i = 0$.

**Determination of $n_i$**

- We first initialize $n_i$ for each $x_i$ as follows:

$$n_i = \begin{cases} c_i + l_i & c_i \geq 1 \\ l_i + 1 & c_i = 0 \text{ and } l_i \neq 1 \\ 1 & c_i = 0 \text{ and } l_i = 1 \end{cases}$$

- We distribute $n - \sum n_i$ between all $T_r$ at random.

To show that these steps are possible, it is enough to show that $\sum n_i \leq n$. By the proof of part 2 of Theorem 3, it is enough to show that $\beta \leq n - k + 1$. The number of vertices for which $l_i \neq 1$ and $c_i = 0$, $\beta$, is as follows:
1. If $|G_1| < k - 1 + 1$, then $\beta = |G_1|$.
2. If $|G_2| \geq k - l + 1$, then $\beta = |G_1| + |G_2| - k + 1$.
Since $|G_1| + |G_2| = d - |G_1|$ and $|G_1| \geq d - l - n$, $|G_1| + |G_2| \leq n - l$, in both cases, $\beta \leq n - k + 1$.

**Algorithm for the determination of $n_i$**
1. Initialize $n_i$ for each $x_i$
2. if $c_i = 1$
3. then $n_i = c_i + l$
4. else if $c_i = 0$ and $l_i \neq 1$
5. then $n_i = l_i + 1$
6. else if $c_i = 0$ and $l_i = 1$
7. then $n_i = 1$
8. Distribute $n - \sum n_i$ between trees related to children of the root ($T_{\alpha}$)

**Constructing ($m,a,b$)-extendable tree**

In this subsection, we will construct a rooted tree $T$ with root $r$, $x_1, \ldots, x_d$ are its children, and $T_{\alpha}$ has $n_i$ vertices, $l_i$ leaves, and $c_i$ labeled internal vertices for which $c_i$ is determined as described earlier. The following algorithm constructs $T_{\alpha}$, $1 \leq i \leq d$.

**Algorithm for the construction of $T$($n_i$, $l_i$, $c_i$)**
1. Let $LS$ be the set of leaf vertices
2. Let $IS$ be the set of internal vertices
3. $IS \leftarrow x_i$
4. $LS \leftarrow \phi$
5. for $j \leftarrow 2$ to $n_i$
6. do if sizeof ($LS$) = $l_i$
7. then $PS = LS$
8. else if $l_i - $ sizeof ($LS$) = $n_i - j + 1$
9. then $PS = IS$
10. else $PS = LS \cup IS$
11. select vertex $v$ from $PS$ randomly and put the new vertex, $w$, as $v$'s child
12. $LS = LS \cup w$
13. if $v \in LS$
14. then $LS \leftarrow LS - v$
15. $IS \leftarrow IS \cup v$
16. Mark $c_i$ vertices from $IS$.

Now, we add the root $r$ and edges $rx_i$, $1 \leq i \leq d$. The desired tree $T$ is constructed. To label the vertices of $T_{\alpha}$, $1 \leq i \leq d$ and root $r$ and the leaves of $T$, we assign $\{1, 2, \ldots, k\}$ to the labeled vertices of $\bigcup T_{\alpha}$ randomly.

In this algorithm, we first construct all ordered pairs ($l$, $d$) that satisfy the conditions of Theorems 2 and 3. Then, we choose some of these pairs randomly and construct all $d$-tuples ($l_1$, $\ldots$, $l_d$), satisfying the conditions of Theorems 2 and 3 and $l = l_1 + l_2 + \ldots + l_d$. Now, one of the $d$-tuples is chosen randomly. Then, we classify $x_i$ according to $l_i$. Using this classification, we consider a primary class for $c_i$. Now, for the remaining vertices for which we have not assigned any $c_i$, we choose a $c_i$ randomly. For calculating $n_i$, we first assign an initial value for each vertex $x_i$ and then distribute $n - \sum n_i$ randomly. It should be noted again that by randomness, we mean distribution according to a uniform random variable.

We also define a function $w$ on the labeled vertices of the $(k,n)$-complete tree, $T$, such that $(T,w)$ becomes an $(m,a,b)$-tree (Figure 5). We obtain $w$ from the following recursive algorithm:

$$w_o(u) = \begin{cases} a & \text{if } u \text{ is a leaf of } T \\ 1 & \text{if } u \text{ is a labeled vertex} \end{cases}$$

We define $w_{o+1}$ recursively from $w_o$ as follows: If there exists $x_i$ such that the MAF of $x_i$ in $(T, w)$ is less than $b$, we choose an arbitrarily labeled vertex from $T_{x_i}$ such as $u$, and define $w_{o+1}(u) = w_o(u) + 1$. We continue this procedure until we obtain the function $w_I$ such that $\sum_{u \in T} w_I(u) = m$ or the MAF of $x_i = b$ for all $1 \leq i \leq d$. Now, $w$ is defined by $w = w_I$ if $\sum_{u \in T} w_I(u) = m$. For the case that $\sum_{u \in T} w_I(u) < m$, we consider $w$ by

$$w(u) = \begin{cases} m - \sum_{u \in T} w(u) & \text{if } u = r \\ w(u) & \text{if } u \neq r \end{cases}$$

Let the vertex $u$ of $A_{x_i}$ have labels $r_o$ and $w(u) = 0$. We repeat row $r_o$ of $A_{x_i}$ $t$ times. Let $B$ be the matrix obtained from $A_{x_i}$ by repeating the procedure. It is obvious that $B$ has $m$ rows, $n$ columns, and $k$ nonidentical rows. Let $u$ be a column of $B$ and a vertex of $(T, w)$. Consider $T_u$ and one of its leaf, such as $u_o$, with label $r_o$. We know that $w(u_o) = a$. The entry of $A_{x_i}$ in column $u_o$ and row $r_o$ is 1. Therefore, by Lemma 2, the entry of $A_{x_i}$ in column $u$ and row $r_o$ is also 1. Since we repeat row $r_o$ in $B$ at least $a$ times, the MAF of column $u$ in $B$ is at least $a$. On the other hand, let $x_i$ be the ancestor of $u$. Since $w(u) \leq w(x_i)$ and $\text{MAF}(x_i) \leq b$ by observation $O_1$, $\text{MAF}(u) \leq b$. Therefore, $(k,a,b)$-PPM.

**Running time of the algorithm**

This algorithm has five steps. In the first step, the algorithm finds $d$, $l$, and $l_1, \ldots, l_d$, which satisfy the necessary conditions in $O(n^2)$. In the second step, the algorithm finds the $n_i$ and $c_i$ for $1 \leq i \leq d$. In the third step, the algorithm constructs $T_{\alpha}$, $1 \leq i \leq d$, with $n_i$ internal vertices, $c_i$ labeled internal
vertices, and \( f \) in \( O(n^3) \). As \( \sum_{i=1}^{d} n_i \leq n \) and \( \sum_{i=1}^{d} n_i^2 \leq n^2 \), the running time of the algorithm in this part is \( O(n^3) \). In the next step, the algorithm defines a function on labeled vertices and finds its value recursively. As this function is called at most \( m \) times and in each call updating MAF of \( x_i \)'s takes \( O(n) \), the running time of the algorithm in this part is \( O(mn) \). In the last step, the algorithm constructs the desired matrix from the tree in \( O(nm) \). Thus, the total running time of the algorithm is \( O(\max(n^2, nm)) \).

**Discussion**

In this article, we have presented a new model for perfect phylogeny matrices. Our goal was to construct a random perfect phylogeny matrix with \( k \) different haplotypes, \( n \) SNPs, and a population size of \( m \) for which the MAF of each SNP is between two specific numbers \( a \) and \( b \). Our new approach allows us to find the necessary and sufficient conditions for the existence of such a matrix. As the solution matrix is a binary matrix with \( m \) rows and \( n \) columns, any algorithm for this problem is \( \Omega(mn) \). We developed an \( O(\max(n^2, mn)) \) time algorithm based on this model to solve this problem.

We used the available methods to construct the perfect phylogeny matrix without taking MAF into account, and we then eliminated those columns that do not satisfy the MAF condition. It should be noted that there are two problems concerning this approach. First, we need to use an algorithm that is able to calculate the MAF of each column automatically and eliminate it if the conditions are not satisfied. Second, it is very probable that the number of columns that should be removed is very high. So, we will obtain matrices with few columns, and we have to run the algorithm several times to obtain a matrix with \( n \) columns and the required MAF. Therefore, an algorithm that could construct such matrices is of much interest. We have developed software, RAPPER, for implementing this algorithm, which is available at http://bioinf.cs.ipm.ir/softwares/RAPPER.
