Abstract: Post-operative inflammation in cancer patients can be modulated by drugs and diets, but evidence on its prognostic role, which would be crucial for personalized treatment and surveillance schemes, remains rather limited. We aimed to systematically review and meta-analyse studies on the prognostic value of post-operative C-reactive protein (CRP)-based inflammatory biomarkers among patients with colorectal cancer (CRC) (PROSPERO#: CRD42022293832). PubMed, Web of Science and Cochrane databases were searched until February 2023. Studies reporting associations between post-operative CRP, Glasgow Prognostic Score (GPS) or modified Glasgow Prognostic Score (mGPS) with overall survival (OS), CRC-specific survival (CSS) and recurrence-free survival (RFS) were included. Hazard ratios (HRs) with 95% confidence intervals (CIs) for the predictor-outcome associations were pooled using R-software, version 4.2. Sixteen studies (n = 6079) were included in the meta-analyses. Elevated post-operative CRP was a predictor of poor OS, CSS and RFS compared with low CRP levels [HR (95% CI): 1.72 (1.32–2.25); 1.63 (1.30–2.05); 2.23 (1.44–3.47), respectively]. A unit increase in post-operative GPS predicted poor OS [HR (95% CI): 1.31 (1.14–1.51)]. Moreover, a unit increase in post-operative mGPS was associated with poor OS and CSS [HR (95% CI): 1.93 (1.37–2.72); 3.16 (1.48–6.76), respectively]. Post-operative CRP-based inflammatory biomarkers have a significant prognostic role for patients with CRC. Prognostic value of these easy-to-obtain routine measurements thereby seems to outperform most of the much more complex blood- or tissue-based predictors in the current focus of multi-omics-based research. Future studies should validate our findings, establish optimal time for biomarker assessment and determine clinically useful cut-off values of these biomarkers for post-operative risk-stratification and treatment-response monitoring.

Keywords: C-reactive protein, survival, assess, risk-stratification, treatment-response

Introduction

Colorectal cancer (CRC) remains the second most common cause of cancer death worldwide despite improvements in early detection, surgical techniques, and chemoradiotherapy.¹ Prognosis most strongly depends on stage at diagnosis, with 5-year relative survival ranging from above 90% for stage I to less than 20% for stage IV cancers.² However, evidence on prognostic factors besides and within stages, which would be crucial for personalized treatment and surveillance schemes, remains rather limited.

CRC prognosis is strongly linked to host inflammatory response at both tumor micro-environment and systemic levels.^{3,4} In recent years, an increasing number of studies have reported post-treatment inflammatory blood biomarkers to

be predictive of CRC outcomes.^{5–12} While inflammation can be reduced by anti-inflammatory drugs^{13–15} and diets with low dietary inflammation scores,^{16–18} comparative and integrative evaluation of clinical relevance of post-operative inflammatory response is limited due to heterogeneity in key design features of pertinent studies, such as selection of inflammatory markers, definition of cut-offs, timing of blood draw, length of follow-up, specific survival endpoints assessed and covariates adjusted for.

The most widely reported inflammatory marker in cancer research is C-reactive protein (CRP), whose analysis in cancer monitoring is routine, relatively cheap, and simple.¹⁹ Serum CRP has been reported as a useful CRC prognosticator, either alone or in combination with albumin as is the case with the Glasgow Prognostic Score (GPS) and the modified Glasgow Prognostic Score (mGPS).²⁰ High GPS and mGPS are reflective of an elevated inflammatory response and poor nutritional state.²¹ In this systematic review and meta-analysis, we aim to evaluate and summarize the evidence on the prognostic value of post-operative serum CRP-based parameters (CRP, GPS and mGPS) among CRC patients with respect to various survival outcomes.

Materials and Methods

The protocol of this systematic review was registered in the international prospective register of systematic reviews (PROSPERO, registration no. CRD42022293832). For the systematic review, the Preferred Reporting Items for Systematic Reviews and Meta-analysis (PRISMA) guidelines were followed and presented in the [Supplementary Material “Prisma Checklist”](#).²² For meta-analysis, the Meta-analyses of Observational Studies in Epidemiology (MOOSE) guidelines were followed.²³

Search Strategy and Data Extraction

The targets for this review were original observational studies focusing on post-operative serum CRP-based parameters (CRP, GPS and mGPS) as predictors of survival outcomes among patients with CRC. The outcomes of interest were overall survival (OS), CRC-specific survival (CSS) and recurrence-free survival (RFS). Unpublished studies, abstracts, reviews, dissertations, theses, editorials, study protocols, clinical guidelines, commentaries, and letters were excluded. We further excluded studies that did not have details of CRP-based biomarker measurement times with respect to surgery, reported exposure-outcome associations based on pre-operative CRP-based biomarkers, did not report on any of the survival outcomes of interest, or had patients who did not undergo surgical treatment for CRC. Studies were included in a meta-analysis if they had reported hazard ratios (HRs) and 95% confidence intervals (CIs) for the associations between post-operative serum CRP-based parameters and any of the listed CRC outcomes of interest.

Systematic searches were conducted using Medline (PubMed interface), the Cochrane Central Register of Controlled Trials (CENTRAL), and ISI Web of Science databases from inception until February 2023. Non-English publications were excluded. The EndNote software version 9 was used for reference management. Two researchers (T.G and A.Z) with the help of a librarian conducted the searches and screened studies for review inclusion. The PRISMA study flow diagram is provided in [Figure 1](#) and the search strings are given in [Supplementary Table 1](#). For database searches, we used medical subject headings (MeSH), free-text words, synonyms, and related terms for the concepts “colorectal neoplasm”, “serum inflammatory marker”, “post-operative”, “prognosis” and “survival”.

From included studies, two researchers (T.G, A.Z) independently extracted the following data: first author, publication year, country, number of participants, cancer stage, cancer site, sex, mean/median age, time of blood sample collection, predictor serum marker, CRC prognostic outcomes, hazard ratios (HRs) and 95% confidence intervals for the predictor-outcome associations. When possible, the most adjusted estimates of HRs were extracted. Disagreements arising after independent data extraction were resolved by further review and discussion in consultation with all authors. For studies that did not report on any of the predefined data domains, contacts were made to request for the additional details from the corresponding authors.

Figure 1 PRISMA flow chart.

Assessment of Study Quality

The Quality In Prognosis Studies (QUIPS) tool was independently used by two researchers (T.G, A.Z) to assess the risk of bias for individual studies.^{24,25} Studies were judged as of low, moderate or high risk of bias based on six domains of study participation, attrition, prognostic factor measurement, outcome measurement, confounding, and statistical analysis and reporting. In cases of critical point disagreements between the two researchers, consensus was reached by further discussion among all authors.

Statistical Analyses

For a given predictor, meta-analysis was conducted if at least two studies reported on the predictor-outcome association. Random effects meta-analysis was applied on the corresponding HRs using the inverse variance method for pooling. For the meta-analyses, the values of the predictor variables were categorized as shown in [Supplementary Table 2](#). The HRs of the individual studies and the pooled HR were visualised in forest plots. The restricted maximum likelihood estimator was used for estimation of the between-study variance τ^2 . The I^2 statistic, expressing the percentage of total variability due to study heterogeneity, was calculated. Testing for heterogeneity was performed using Cochran's Q-test. Where possible, publication bias was assessed using Egger's linear regression test of funnel plot asymmetry. In addition, sensitivity analyses were conducted by assessing the effect of time of blood collection on prognostic associations and excluding studies that had not adjusted for key covariates (age and stage). All statistical analyses were conducted with R-software 4.2 using the package "meta", version 5.5.²⁶ All p-values were two-sided, and significance level was set at 0.05.

Results

Literature Search

The PRISMA flow diagram for study selection is depicted in [Figure 1](#). A total number of 9242 individual studies were reviewed, and of those, 89 were considered in the full-text screening. In addition, by examining the reference lists of included studies, we identified two additional studies that were not captured through the initial search strategy. A list of studies excluded in the full-text selection and the respective exclusion criteria can be found in [Supplementary Table 3](#).

Study Characteristics

General information about the included studies is provided in [Table 1](#). A total of 19 studies were included in the systematic review, with sample sizes ranging from 147 to 813 and a total number of 6895 patients. Eight studies were conducted in the United Kingdom (UK),^{27–34} six in Asia,^{21,35–39} one in the United States⁴⁰ and the rest originated from the European region.^{41–44} Twelve studies used serum CRP levels as a prognostic predictor, five used GPS and four used mGPS for prognostication. In six studies, blood samples for laboratory analysis were collected within a week after surgery, while in ten studies blood samples were collected between one and six months after surgery. For prognostic analysis, most of the studies where blood samples were taken one or more months after surgery used cut-off points of 10 mg/L and 35 g/L for CRP and albumin, respectively. Much higher cut-offs for CRP (mostly >150 mg/L, range 150 to 170 mg/L) and a lower cut-off for albumin (25 g/L) were used in the studies collecting blood samples within a week after surgery. Eleven studies adjusted for at least age and cancer stage (TNM or Duke's). [Supplementary Table 4](#) shows other covariates adjusted for in the included studies such as sex, comorbidities, surgical procedure, use of neoadjuvant/adjuvant therapy, and surgical complications. Quality assessment results based on QUIPS are reported in [Supplementary Table 5](#) and presented in [Figure 2](#). High risk of bias was observed for the domain of study confounding in five studies.^{21,33,35,36,39}

C-Reactive Protein and CRC Prognostic Outcomes

Results of studies investigating the association between post-operative CRP and survival showed that elevated CRP was a significant predictor of poor OS, CSS and RFS compared with low CRP levels [HR (95% CI): 1.72 (1.32–2.25); 1.63 (1.30–2.05); 2.23 (1.44–3.47), respectively] ([Figure 3](#)). Substantial heterogeneity was observed in the meta-analysis of nine studies on the association between CRP and OS ($I^2 = 70\%$, $p < 0.01$) ([Figure 3A](#)). Therefore, sensitivity analyses were conducted to investigate the sources of heterogeneity. The pooled result of five studies^{28,40–43} investigating the relationship between CRP assessed within four weeks to four months post-operatively (cut-off = 10mg/L) and OS showed more than 2-fold hazard ratio for those above the cut-off (HR, 95% CI: 2.24, 1.45–3.44) ([Figure 4A](#)). Considerable heterogeneity ($I^2 = 69\%$, $p < 0.01$) was observed for this meta-analysis. When restricting the analysis to the three studies that had adjusted for age and cancer stage, an even stronger association with no heterogeneity was observed (adjusted HR, 95% CI: 2.40, 1.60–3.61) ([Figure 4B](#)). Meta-analysis for three studies on the association between CRP assessed within a week after surgery (cut-off range = 150–170mg/L) and OS also showed a significant albeit weaker association (HR, 95% CI: 1.50, 1.12–2.01) ([Figure 4C](#)). For this meta-analysis, the percentage of between-study heterogeneity was 39% and only one study adjusted for age and cancer stage.³² Notably, the association was much stronger in that single study (adjusted HR, 95% CI: 2.14, 1.34–3.41) than in the two studies without such adjustment.

The pooled result of two studies showed approximately 2-fold higher risk for poor CSS among patients whose CRP assessed at four months post-operatively was above 10mg/L (HR, 95% CI: 1.93, 1.34–2.79) ([Figure 4D](#)). A weaker but significant relationship between CRP and CSS was also seen in the meta-analysis of four studies that assessed CRP within one week post-operatively (cut-off range = 150–170mg/L) (HR, 95% CI: 1.52, 1.16–1.97) ([Figure 4E](#)). One of these studies by McSorley et al adjusted for multiple covariates including sex, tumor-node-metastasis (TNM) stage and surgical complications.³²

Glasgow Prognostic Score and CRC Prognostic Outcomes

Meta-analysis of two studies^{33,34} investigating the relationship between GPS determined within a week post-operatively and OS showed approximately 30% higher risk for poor OS for each unit increase in GPS (HR, 95% CI: 1.31, 1.14–1.51)

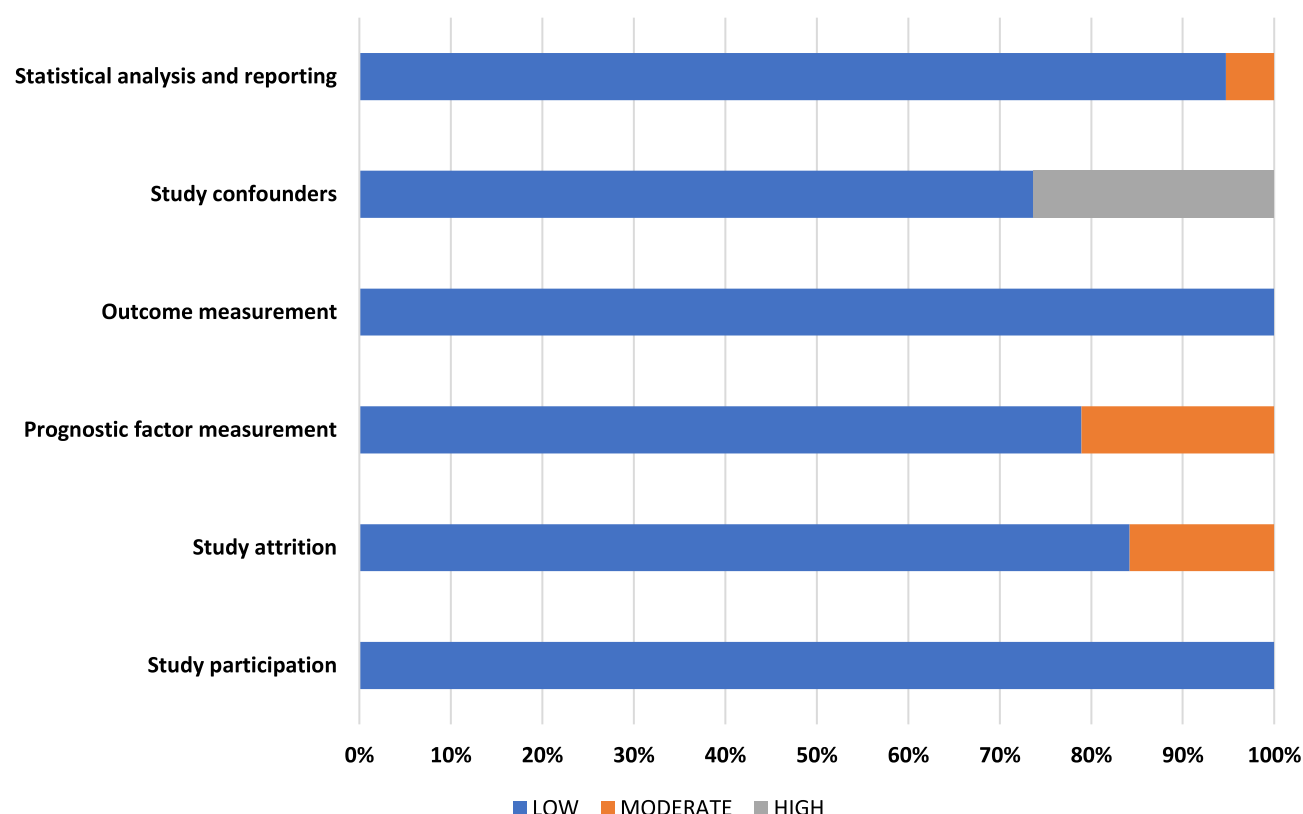

Figure 2 Graphical presentation of quality assessment of 19 studies included in the systematic review (QUIPS risk of bias assessment).

(Figure 5A). Two other studies investigating the association between GPS measured four weeks after surgery suggested a stronger association with OS, but results could not be combined in a meta-analysis because of different coding of GPS in the analysis. One study³⁷ reported an adjusted HR (95% CI) of 1.66 (0.98–2.80) per unit increase in GPS while the other one³⁵ reported a HR (95% CI) of 1.98 (0.93–4.21) comparing combined GPS 1 and 2 with GPS 0 without controlling for any covariates.

Modified Glasgow Prognostic Score and CRC Prognostic Outcomes

Meta-analysis of two studies^{30,37} investigating the relationship between mGPS determined \geq four weeks post-operatively and OS showed approximately 2-fold higher risk for poor OS for each unit increase in mGPS among patients with CRC (adjusted HR, 95% CI: 1.93, 1.37–2.72) (Figure 5B). Pooled results of two studies^{30,31} investigating the relationship between mGPS assessed \geq four weeks after surgery and CSS showed a particularly strong association per unit increase in mGPS [HR (95% CI): 3.16, 1.48–6.76] (Figure 5C). Both studies were from the UK but one study³⁰ adjusted for at least age and cancer stage.

Discussion

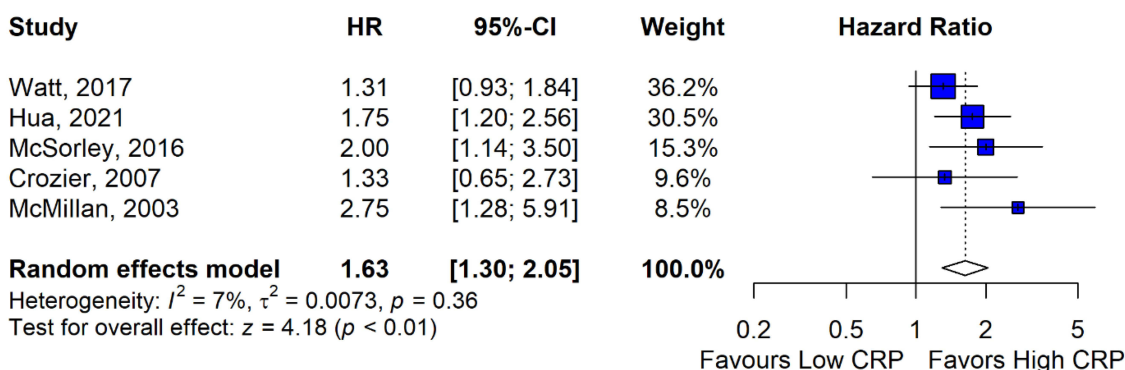

To the best of our knowledge, this is the first systematic review and meta-analysis evaluating the prognostic value of CRP-based post-operative inflammatory response and CRC survival. Our results show substantially increased risk for poor survival among patients with elevated CRP, GPS and mGPS measured four or more weeks after surgery.

Epidemiological studies have recently shown that CRP, GPS and mGPS are significant predictors of survival in different cancers including CRC.^{45,46} Although the exact mechanisms on how CRP and albumin are linked to CRC prognosis after surgery are elusive, post-operative tissue injury, infection, or residual tumor cells have been reported to induce immune-cell-mediated acute or chronic inflammation.^{47,48} Activation of immune cells promotes release of several pro-inflammatory cytokines, such as interleukin-6 (IL-6), IL-1, and tumor necrosis factor α (TNF- α).⁴⁹ In addition, pro-inflammatory diets may increase serum levels of IL-6, CRP and TNF- α particularly for CRC patients with a low count of

tumor-infiltrating lymphocytes.¹⁸ In liver hepatocytes, pro-inflammatory cytokines induce CRP production while suppressing albumin production. Elevated CRP increases expression of oncogenes resulting in DNA damage, impaired immune function, cell proliferation, angiogenesis, apoptotic resistance, tumor growth, invasion, and progression.⁵⁰ On the other hand, hypoalbuminemia may reduce tolerance to anticancer drugs and therefore increase therapeutic toxicity.⁵¹ Given this background, it seems plausible that post-operative serum CRP and albumin may be valuable prognosticators for CRC patients undergoing potentially curative resection.

Our meta-analyses suggest that CRC patients with elevated serum CRP levels ($\geq 10\text{mg/L}$) four or more weeks after surgery have an increased risk for poor prognosis compared with patients who have normal CRP levels ($<10\text{ mg/L}$). CRP

assessments done within a week after surgery also showed associations with survival, but such associations were reported for much higher CRP elevations (≥ 150 mg/L) and summary estimates of HRs from meta-analyses were lower than those for CRP measurements done four or more weeks after surgery. Higher CRP levels within a week after surgery may predominantly reflect consequences of surgical stress and wound healing, which may be overcome to a large extent after four weeks. Consequently, inflammatory biomarkers assessed within four weeks after surgery may be less predictive of long-term prognosis than CRP elevations beyond this period.

GPS and mGPS are metrics based on a combination of the acute phase proteins CRP and albumin, which are reflective of an individual's immune and nutritional status. Elevated GPS and mGPS reflect abnormally high CRP and/or hypoalbuminemia. According to our meta-analysis, elevated GPS and mGPS assessed four weeks to six months following surgery are strongly associated with worse overall survival of CRC patients. Furthermore, a unit increase in mGPS assessed four weeks after surgery was associated with about three times higher risk for poor CRC-specific survival. These findings are consistent with previous studies that have reported a significant independent predictive role of CRP/Albumin for recurrence of other cancers such as renal cell carcinoma,^{52–54} esophageal cancer,^{55,56} hepatocellular carcinoma,⁵⁷ cholangiocarcinoma,⁵⁸ and nasopharyngeal cancer.⁵⁹

In addition to the already discussed role of elevated CRP in CRC prognosis, hypoalbuminemia may account for poor prognosis observed in patients with elevated GPS or mGPS. In a previous systematic review and meta-analysis of studies with over 1.49 million participants with various disease conditions, high serum albumin levels (>35 g/L) were strongly associated with better overall survival (HR, 95% CI = 0.66, 0.55–0.77) and cancer-specific survival (HR, 95% CI = 0.65, 0.48–0.88).⁴⁵ Other studies have also reported poor overall survival for patients with low serum albumin levels in various conditions including diabetes,⁴⁶ cardiovascular disease,^{60,61} COVID-19,^{62–66} kidney disease,⁶⁷ and liver cirrhosis.^{68–71} Thus, dysregulation of albumin in CRC patients may be predictive of poor prognosis possibly reflecting an impaired immune and liver function, poor nutritional status or a compromised therapeutic tolerance.⁷²

Potential Clinical Implications and Need for Further Research

How to best monitor course of disease of CRC patients, enable personalized judgment of prognosis and make best possible personalized post-operative treatment decisions is subject to intensive ongoing research. However, most biomarkers are strongly related to stage at diagnosis and provide rather limited prognostic value beyond tumor stage. This particularly applies to biomarkers that are either up- or downregulated prior to surgery. In addition, biomarkers measured shortly after surgery, for example during the hospital stay following surgery, may primarily reflect surgical stress and post-surgical wound healing and be less relevant for judgment of long-term prognosis. Our results suggest that measurement of CRP, GPS and mGPS in blood samples taken four weeks to six months after surgery could be more helpful in this respect. Given that they can be easily measured at low cost in almost any standard laboratory, their measurement could be easily implemented in routine clinical care. Further research is needed, however, to evaluate the use of their prognostic information for enhanced, personalized post-operative care and surveillance. If and to what extent these biomarkers may also be helpful for evaluating efficacy of further (post-operative) treatments or measures of tertiary prevention, should also be addressed in future research. While a significant number of individual studies (7 in total) included patients with stage IV cancer, we could not conduct subgroup analyses by stage because studies did not report stage-stratified results (probably because of small sample sizes). We suggest future studies to be designed with this in mind and ascertain if these prognostic biomarkers may be useful in palliative care settings.

Strengths and Limitations

Most studies included in our review were of high quality for the various domains assessed for quality. However, despite the comprehensive literature search, we cannot rule out having missed non-English studies that were excluded because of inadequate resources. Furthermore, there was heterogeneity in the degree of adjustment for covariates. In particular, some studies did not adjust for any covariates. This would be a major concern if the aim was to assess the causal role of inflammation. However, our focus was on the use of the inflammation-related markers for prognostication. Interestingly, associations for CRP and mGPS with overall survival persisted or increased rather than decreased when meta-analyses were restricted to studies with covariate adjustment. These patterns suggest that these biomarkers may be useful to refine assessment of survival perspectives beyond

the established prognostic criteria such as stage at diagnosis. Carefully planned future studies should provide associations with different levels of adjustment to better delineate the prognostic value of CRP-based markers beyond established prognostic criteria. Future studies should also address potential differences in the prognostic value of CRP-based blood markers between men and women.

Variations in adjuvant therapies, lifestyle, environmental and genetic factors across patient cohorts from different countries may also be a source of heterogeneity. While there is limited evidence on ethnic variations of CRP/albumin serum levels, a previous study has reported significant variations in a leucocyte-based inflammatory response parameter among Europeans, East Asians, Black Americans, Hispanic Americans, and White Americans.⁷³ Nevertheless, the consistency of our results across study populations suggests that the prognostic role of CRP-based biomarkers may hold in a wide range of different populations. However, the small number of studies identified for each association hindered to address this in more detail and also hindered meaningful analysis of publication bias. Furthermore, many included studies did not provide details of technologies and methods of serum assays which may vary widely.

Conclusions

This systematic review and meta-analysis of patient cohort studies suggests that serum CRP-based biomarker levels, measured four weeks or more weeks after surgery, could be an easy-to-determine highly informative prognostic marker for CRC patients. In particular, they could provide important incremental prognostic information that is independent of tumor stage, age, and other established prognostic markers. Potential applications, to be corroborated, validated and expanded in further research may be possible use of CRP-based biomarkers for long-term monitoring of the course of the disease, risk stratification for treatment decisions, and evaluation of the efficacy of post-operative treatment and tertiary prevention measures.

Clinical Epidemiology

Dovepress

Publish your work in this journal

Clinical Epidemiology is an international, peer-reviewed, open access, online journal focusing on disease and drug epidemiology, identification of risk factors and screening procedures to develop optimal preventative initiatives and programs. Specific topics include: diagnosis, prognosis, treatment, screening, prevention, risk factor modification, systematic reviews, risk & safety of medical interventions, epidemiology & biostatistical methods, and evaluation of guidelines, translational medicine, health policies & economic evaluations. The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use.

Submit your manuscript here: <https://www.dovepress.com/clinical-epidemiology-journal>
