Abstract: Diabetes mellitus (DM) is a chronic metabolic disease characterized by elevated blood glucose levels, resulting in multi-organ dysfunction and various complications. Fusion proteins can form multifunctional complexes by combining the target proteins with partner proteins. It has significant advantages in improving the performance of the target proteins, extending their biological half-life, and enhancing patient drug compliance. Fusion protein-based drugs have emerged as promising new drugs in diabetes therapeutics. However, there has not been a systematic review of fusion protein-based drugs for diabetes therapeutics. Hence, we conducted a comprehensive review of published literature on diabetic fusion protein-based drugs for diabetes, with a primary focus on immunoglobulin G (IgG) fragment crystallizable (Fc) region, albumin, and transferrin (TF). This review aims to provide a reference for the subsequent development and clinical application of fusion protein-based drugs in diabetes therapeutics.

Keywords: diabetes mellitus, fusion protein, Fc protein, glucagon-like peptide 1 receptor agonists, transferrin, albumin

Introduction

Diabetes mellitus (DM) is a chronic metabolic disorder characterized by elevated glucose in the blood levels (hyperglycemia). Prolonged metabolic disorders can result in systemic damage to various organs including the kidneys, eyes, heart, blood vessels and nerves, leading to chronic progressive lesions, hypofunction, and organ failure.¹⁻³ According to the 10th edition of the IDF diabetes atlas released by the International Diabetes Federation (IDF), the global number of people with DM is as high as 537 million, and its prevalence is increasing annually.⁴

Type 1 diabetes mellitus (T1DM) is characterized by the autoimmune-mediated destruction of pancreatic β -cells, resulting in an absolute lack of insulin secretion and is most commonly diagnosed in children and adolescents.^{4,5} Type 2 diabetes mellitus (T2DM) is characterized by insulin resistance and a relative lack of insulin secretion, which can cause by various etiologies. T2DM constitutes over 90% of clinical cases and is predominantly observed in middle-aged and elderly individuals.⁶

Currently, the management of diabetes mellitus is based on a globally accepted “five-pronged” approach, encompassing health education, diet control, physical exercise, self-monitoring, and pharmacological intervention. The global market value of diabetes therapeutics drug accounted to \$118.1 billion in 2020, and it is projected to reach \$317.9 billion by 2030, exhibiting a compound annual growth rate (CAGR) of 10.4% from 2021 to 2030.⁷ Fusion protein-based drugs are favored in the market among various diabetes medications due to their extended half-life and stability, which also indicates an increasing market demand with the rise of chronic diseases.⁸ Genetic engineering technology allows for the development of fusion protein-based drugs that combine a functional target protein with a long half-life human-derived IgG Fc protein, albumin, or transferrin. Firstly, this fusion reduces the immunogenicity of the drug in vivo due to the human origin of the partner fusion protein. Secondly, the large relative molecular mass of the partner fusion protein,

along with its unique ultra-long-acting mechanism, it reduces the kidney clearance of the target protein while preserving its original function, therefore extending the duration of drug effect.

Currently, the majority of papers primarily focus on a holistic approach to long-acting proteins, however, they failed to provide a detailed analysis of the target and clinical dosing of fusion protein-based drugs in the field of diabetes drug therapy. Hence, we conducted a systematic review of the fusion process and the targeted actions of various fusion protein-based drugs based on the latest research findings regarding fusion protein drugs used in the treatment of diabetes and its complications (Table 1). The present study aims to provide novel insights into the field of combination drug therapy for diabetes. Additionally, it aims to offer new research clues for the development and utilization of fusion protein-based drugs, as well as explore new possibilities for individualized diabetes treatment.

Diabetes Mellitus

Diabetes is a prevalent chronic illness that affects individuals globally and is characterized by persistent hyperglycemia. It is a significant independent factor contributing to the development of cardiovascular diseases, which has the highest incidence and mortality rates worldwide.²⁸ Diabetes mellitus can be classified into type 1 (T1DM) and type 2 (T2DM) based on the islet function. Islet function failure, with a low insulin release curve, corresponds to T1DM; while relatively intact islet function, characterized by a delayed peak insulin release curve, corresponds T2DM.

The regulatory mechanism of blood glucose is shown in Figure 1.^{29,30} After food intake, increased blood sugar level stimulates insulin secretion by islet β cells. Insulin then binds to the insulin receptor (IR) on the cell surface, promoting the IR phosphorylation. Phosphorylated IR further enhances the phosphorylation of the tyrosine structural domain on the insulin receptor substrate (IRS). This amplifies its active effect via the downstream phosphatidylinositol 3 kinase/protein kinase B (PI3K/Akt2) pathway and continues to phosphorylate downstream effector molecules, such as the Rab-GTPase-activating protein (Rab-GAP).³¹ Ultimately, this process allows Glucose Transporter 4 (GLUT-4) to transfer from the cytoplasm to the cellular membrane, regulating intracellular glucose uptake and utilization.³²

Diabetes mellitus is a multifaceted disease with various etiologies. Different types of diabetes mellitus can be triggered by various factors. T1DM is an intricate autoimmune disease primarily associated with autoreactive memory T cells that fail to recognize their antigens, leading to immune tolerance and subsequent attack on islet β cells.³³ A characteristic feature of patients with T1DM is the presence of T cells with a memory phenotype. These auto-reactive memory T cells are long-lived, highly responsive to antigenic stimuli, and play a significant role in the persistent deterioration of beta cell function in T1DM.³³ Several immune interventions have shown some success in protecting beta cell function, such as Abatacept and Alefacept, which will be discussed below.^{34,35} These interventions have been found to deplete or modulate memory T cells. Well-tolerated specific immunotherapies can improve islet function in patients with T1D and are one of the promising strategies to slow down the process of β -cell destruction after the onset of T1D. A series of autoimmune antibodies for T1DM include: islet cell antibody, insulin autoantibody, glutamic acid decarboxylase antibody, islet antigen-2 antibody, and zinc transporter-8 antibody, which not only predict the likelihood of having T1DM, but also assist in diagnosing it with blood glucose values.³⁶

T2DM is mainly caused by genetics, environmental factors (such as obesity, aging and a high-calorie diet) and inflammation, which promote each other and lead to insulin resistance.^{37,38} For example, chronic inflammation has been implicated in the pathogenesis of obesity-associated T2DM.³⁹ And in turn obesity contributes to the development of chronic low-grade inflammation, as evidenced by elevated circulating levels of inflammatory cytokines.⁴⁰ Inflammation plays a crucial role in the development of T2DM and is also medically controllable in T2DM.^{39,41} Inflammatory factors such as TNF- α , IL-6 and IL-1 β often activate the NF- κ B and JNK pathways through autocrine or paracrine signaling. This further promotes the formations of NLRP3 inflammatory vesicle and the releases of the cytokines and chemokines. Consequently, immune cells are recruited, leading to interference with insulin signaling in the peripheral tissues. These inflammatory factors can be utilized for predicting the risk of T2DM, and improving the corresponding inflammatory process is a common approach in the treatment of diabetes.

Table 1 Related Fusion Protein Analogs for the Treatment of Diabetes

Category	Drug Name	Trade Name	Structure	Ligand	Half-Life	Research Status	Major Adverse Reactions	References
IgG Fc Fusion proteins	Dulaglutide	Trulicity	GLP-1 analogue - IgG4Fc	GLP-1R	5 days	Listed (FDA 2014)	Gastrointestinal adverse reactions	[9–12]
	Efglenatide		Exendin-4 analogue - IgG4Fc	GLP-1R	5.6 to 7.5 days	Clinical Phase 3 trial	Gastrointestinal adverse reactions	[13]
	Basal Insulin Fc /Insulin efsitora alfa		Insulin analogue - IgG2Fc	Insulin receptor	14 days	Clinical Phase 2 trial	Low blood sugar	[14]
	Etanercept	Enbrel	TNFRII- IgG1Fc	Membrane TNFR	3–5.5 days	Listed (FDA 1998) but for T1DM treatment in a small pilot study	Injection site reaction and infections	[15,16]
	Abatacept	Orencia	CTLA-4- IgG1Fc	B7	2 weeks	Listed (2005 FDA) but for T1DM treatment in clinical Phase 2 trial	Upper respiratory tract infection and disgusting	[17,18]
	sgp130Fc / Olamkicept		gp130- IgG1Fc	sIL-6R	4.7 days	Clinical phase 2 trial	Seasonal upper respiratory tract infections and skin diseases	[19]
	Alefacept	Amevive	LFA-3 - IgG1Fc	CD2	12 days	Listed (2003 FDA) but for T1DM treatment in clinical phase 2 trial	Low blood sugar and infection	[20,21]
	Rilonacept	Arcalyst	IL-1R- IgG1Fc	IL-1 α , IL-1 β	6–8 days	Listed (2008 FDA) for T1DM treatment in clinical Phase I trial	Injection site reaction and upper respiratory tract infections	[22]
Albumin Fusion proteins	Albiglutide	Tanzeum	GLP-1 analogue-albumin	GLP-1R	6–8 days	Listed (FDA 2014)	Gastrointestinal adverse reactions and pancreatitis	[23,24]
	Albulin		Insulin-albumin	Insulin receptor	50 hours	Rats		[25,26]
Transferrin fusion protein	ProINS-TF		Proinsulin-Transferrin	Insulin receptor	7.29 hours	Rats		[27]

Figure 1 The signaling pathways and targets of drug action in normal humans after glucose uptake. In normal humans, blood glucose rises after food intakes and stimulates insulin secretion from pancreatic beta cells. Insulin first binds to the insulin receptor (IR) on the cell surface, which phosphorylates the insulin receptor itself, and the activated IR promotes phosphorylation of the tyrosine structural domain on the insulin receptor substrate (IRS), followed by signal transfer to the downstream PI3K/Akt2 pathway to amplify its active effect, and the activated Akt in turn continues to phosphorylate downstream effector molecules, including Rab-GTPase-activating protein, which ultimately translocates glucose transporter 4 (Glut-4)-vesicles from the cytosol to the cell membrane surface, regulating cellular glucose uptake. GLP-1 is known to inhibit glucagon secretion and promote insulin secretion. Dulaglutide, Albiglutide and Efpeglenatide, which are GLP-1 RAs, can lower blood glucose through both processes. IL-6 and TNF- α activation decreases the tyrosine kinase activity of insulin and impedes insulin-mediated glucose uptake in skeletal muscle and glucose uptake by adipocytes, both corresponding to the antagonists Olamkicept and Etanercept, which can block this pathway to achieve a lowering effect on blood glucose.

Abbreviations: IRS1, insulin receptor substrate 1; PI3K, phosphatidylinositol 3 kinase, AKT, protein kinase B; Rab-GTP, Rab-GTPase-activating protein; GLUT4, glucose transporter 4.

Fusion Protein

Since the synthesis of crystalline bovine insulin in China in 1965, the development of synthetic proteins has propelled mankind into an era of significant advancements in proteins drugs.^{42–45} The global protein therapeutics market was valued at \$283.64 billion in 2020, and it is projected to reach \$566.66 billion by 2030, with a compound annual growth rate (CAGR) of 7.1% from 2021 to 2030.⁴⁶ Recombinant proteins are the major component of protein drugs, encompassing 197 recombinant proteins into the market from 2018 to 2022.⁴⁷ The major types of recombinant proteins include monoclonal antibodies, hormones (e.g. insulin), cytokines, and fusion products. Fusion protein-based drugs are one of the long-acting drugs (with a half-life longer than 8 hours),⁴⁸ which are produced by combining the target protein with another protein (Table 2). These fusion protein-based drugs exhibit extended half-life, minimal toxicity, high degree of specificity, excellent targeting capabilities, and remarkable stability, leading to their burgeoning popularity within the biopharmaceutical industry.

Fusion protein-based drugs have three main fusion partners: the Fc fragment, albumin, and transferrin.⁴⁸ The ultra-long-acting preparations of Fc fusion proteins and albumin fusion proteins depend primarily on endogenous proteins in the organism, namely the neonatal Fc receptor (FcRn). This receptor extends their biological half-life by preventing hepatic metabolic degradation through specific receptor-mediated cycling. FcRn is a non-covalent heterodimer composed of a 40 kDa α heavy chain and a 12 kDa β 2m monomeric light chain. The α heavy chain consists of three extracellular regions (α 1, α 2, and α 3), a transmembrane region, and a cytoplasmic tail of 44 amino acids.⁴⁹ Although FcRn has a structure similar to that of the MHC I molecule, it possesses a blocked peptide-binding groove, preventing the presentation of peptide antigens to T cells and avoiding the elicitation of the body's immune response.⁵⁰ FcRn binds

Table 2 Types of Long-Acting Drugs

Category		Strengths	Weaknesses	References
Protein binding	Fc fusion	High homology	Expensive, potential immunogenicity, injectable use only	[48]
	Albumin binding	Low immunogenicity	Expensive and injectable use only	[48]
	Transferrin binding	Oral properties, low price and easily production	Unlisted and insufficient research	[48]
Other bio-molecule binding	PEGylation	Popular, safe, good solubility	Non-biodegradable, immunogenic and injured renal tubular epithelium	[48,58,59]
	Glycosylation	High stability	Close production monitor	[60–62]
Nanoparticle mediated		Oral properties, high stability, good biocompatibility and efficient bio-barrier penetration	Unpredictable drug clearance rate, nano-toxicity	[48,63–65]

to Fc fragments or albumin through a pH-sensitive manner. Antibodies and albumin enter the cell by pinocytosis and bind to FcRn in the acidic endosome (pH=6.0). Subsequently, the FcRn-mediated antibody and FcRn-mediated albumin are released back into the extracellular environment and dissociate from FcRn at a pH of 7.4. This mechanism prevents the degradation of the antibodies and albumin by the acidic lysosomes, which enter the cell via pinocytosis, leading to the development of a long-lasting formulation. Studies have demonstrated that the fusion of FcRn with IgG Fc or albumin has been effective in delivering therapeutic drugs in the lung, oral cavity, genitalia, and uterus.^{51,52} It proves the promising development of Fc fusion protein in clinical applications.

In addition to combining functional proteins with Fc fragments and albumin, transferrin is also used as a bio-carrier for drug delivery, becoming a new fusion form. Transferrin enters the cell in a cytosolic form by binding to Transferrin receptor-1 (TFR1), and subsequently undergoes dissociation in the acidic environment of the endosome. It is then released extracellularly, thereby preventing the degradation of TF and TFR in the lysosome. This process facilitates recycling of transferrin upon release, effectively reusing Transferrin,⁵³ thus improving TF half-life and efficacy. Apart from its application in the treatment of diabetes mellitus through the proinsulin-transferrin fusion protein (ProINS-TF), which will be mentioned later, transferrin can also be used to deliver proteins, drugs or DNA to target cells through diverse binding modalities, including biomolecules and nanoparticle platforms.^{54–57} The binding of transferrin to nanoparticle-coated insulin has demonstrated resistance to enzymatic hydrolysis and the ability to extend insulin efficacy for up to 10 hours.⁴⁹

IgG Fc Fusion Protein

The Overview of IgG Fc Fusion Protein

The IgG Fc fusion protein is a genetically engineered recombinant protein that combines a functional protein with specific biological activities to the IgG Fc fragment. The immunoglobulins contain antigen-binding fragment (Fab) and Fc domain in vivo. The Fab region is composed of four structural domains: Variable Light domain (VL), Constant Light domain (CL), Variable Heavy domain (VH), and Constant Heavy domain-1 (CH-1), which are mainly responsible for antigen recognition. The Fc region, primarily responsible for immunomodulatory functions, encompasses two CH3 and two glycosylated CH2 structural domains located at the C-terminus of the antibody heavy chain. FcRn is mainly expressed in cytoplasm vesicles. Upon entry of the Fc fragment into the endosome through pinocytosis, FcRn interacts with specific amino acid residues at the CH2-CH3 interface under a pH environment of pH=6.^{51,52,66,67} Subsequently, FcRn-IgG detaches from the sorted nucleosomes as vesicles and tubules, fuses with the plasma membrane, and then releases IgG Fc fragments through exocytosis at pH=7.4.

Unbound IgG, which does not bind specifically to FcRn, remains within the vesicles of the sorted nucleosomes. It undergoes gradual acidification and maturation, eventually being disassembled by lysosomal enzymes.^{66,68} By virtue of the long-lasting mechanism of Fc binding to FcRn and immunity to lysosomal degradation *in vivo*, IgG exhibits a half-life up to 20 days.

In addition to the FcRn-mediated recycling mechanism,⁵³ the remarkable extended half-life of Fc fusion proteins can be attributed to the following three factors: (1) Fc fusion protein greatly increases the spatial size of the protein and peptide drugs, surpassing the 20,000–40,000 Da threshold for glomerular filtration, thereby reducing the glomerular filtration rate of Fc protein.

Reducing the glomerular filtration rate of Fc protein. (2) The human-derived Fc fragment reduces the immunogenicity of the fusion protein, preventing elimination by the immune system. (3) The Fc fusion protein retains the hinge region of the natural linker IgG, which can prevent the interaction between two fused molecules and thus improve stability. The structure and function of the functional protein and the Fc fragment are relatively independent without interference, meanwhile, the Fc fragment is shielded from degradation by FcRn, which allows the fusion protein to have a longer effect.

The Selection of IgG Fc Fragment

The application of Fc fragments is not limited to IgG, studies have shown that IgA, IgE and IgM can also serve as effective alternatives to IgG for the therapeutic application. IgA or IgE recombinant proteins enhances antibody-dependent cell-mediated cytotoxicity (ADCC) and possess significant advantages in targeting and eliminating tumor cells. Moreover, utilizing the Fc fragment of IgE as a fusion protein promotes T cell proliferation.^{69–72} The Fc fragment of IgM exhibits anti-microbial activity by augmenting complement-dependent cytotoxicity (CDC) and can be employed as a subunit vaccine component to induce a robust and lasting immune response.^{73–75}

Compared with other plasma proteins, IgG is currently the most advantageous plasma protein with natural long half-life protein not only taking up a large amount in serum and non-mucosal tissue, but also exhibiting a half-life from 2–4 weeks.⁷⁶ IgG has classified into four categories based on disulfide bonds and amino acids composition in the hinge region. According to the descending order of serum concentration, it can be classified into IgG1 (60–70%), IgG2 (20–30%), IgG3 (5–8%) and IgG4 (1–3%).⁷⁷ IgG1 peaks in plasma antibodies, and FcγRIII bonding mediates strong ADCC, CDC and ADCC (antibody-dependent cell-mediated phagocytosis). It is the most commonly used isoform of recombinant antibodies in antitumor therapy. IgG3 is the most functional subclass due to its high affinity for FcγR, activating complements and promoting FcγR-mediated function more effectively than any other immunoglobulin subclass.^{78,79} However, in virtue of its low affinity for FcRn, short half-life, and susceptibility to hydrolysis in the hinge region, its application is quite limited and no drugs of this subtype are available in clinical practice.^{79–81} The ADCC, ADCC and CDC of IgG2 and IgG4 are relatively weak and minimally harmful little damage to tissue cells. In the development of therapeutic fusion proteins, less cytotoxic Fc fragments of IgG2 and IgG4 are usually chosen as fusion vectors to minimize potential side effects.

Glucagon-Like Peptide 1 Receptor Agonists

Glucagon-like peptide-1 (GLP-1) is a type of enteroglucagon that is primarily secreted by L cells located in the distal small intestine and colon. GLP-1 exerts multiple physiological effects by binding to G protein-coupled receptors widely distributed throughout the body, thereby lowering blood glucose levels and improving insulin resistance.^{82,83} In the pancreas, it increases glucose-dependent insulin secretion, inhibits glucagon secretion, and protects pancreatic β cells.^{84,85} In the gastrointestinal tract, it delays postprandial gastric emptying, thereby delaying intestinal glucose absorption and reducing body weight.^{84,86} In the liver, it decreases glucose output and increases glycogen storage.⁸⁷ In the heart, it increases glucose utilization and reduces lipid metabolism. This results in lower blood pressure and higher cardiac function, which offers cardioprotection and reduces the risk of cardiovascular events in patients.^{88,89} In the brain, it promotes satiety and reduces appetite through central suppression.⁸⁷ However, the plasma half-life of endogenous GLP-1 is only about 2 minutes due to specific cleavage at the N-terminal by dipeptidyl peptidase-IV (DPP-IV), and the inherent high renal clearance of small molecule peptides.

Currently, there are ten GLP-1 receptor agonists (GLP-1RAs) approved for marketing: Exenatide, Liraglutide, Dulaglutide, Lixisenatide, Albiglutide, Semaglutide (two dosage forms: subcutaneous injection and oral administration), Tirzepatide, Efpeglenatide, PEG-Loxenatide and Beinsaglutide, all of which can be used in the treatment of type 2 diabetes.^{90–93} These GLP-1RAs have a similar physiological function to GLP-1, but with a considerably longer half-life. The main adverse effects in subjects treated with GLP-1 RAs were gastrointestinal effects such as nausea, vomiting and diarrhoea.^{94,95}

Dulaglutide

Dulaglutide is a long-acting GLP-1RA developed by Eli Lilly and Company and was ratified by the FDA for marketing in 2014.

To extend its half-life, Lilly employed a fusion approach by linking the C-terminus of 2 GLP-1s (7–37) with the N-terminal end of the IgG4 Fc fragment via a small molecule peptide chain. An optimized splice sequence was introduced to link the the GLP-1 and the hinge region of IgG4 Fc, thus restoring the full potency of the functional protein GLP-1 through specific amino acid site modifications, rendering it impervious to DPP-IV enzymatic degradation.⁹⁶ Additionally, this process eliminates potential T-cell epitopes to reduce immunogenicity, resulting in the development of Dulaglutide, a highly effective, long-acting GLP-1 receptor agonist (GLP-1RA) possessing a 90% homology with GLP-1.

A prominent distinguishing characteristic of Dulaglutide different from other classes of oral hypoglycemic drugs is that it can protect β cells and avoid progressive β cell function decline.^{97,98} Compared with the traditional drugs metformin, exenatide injection and sitagliptin phosphate^{99–101}, Dulaglutide exhibits superior efficacy in managing hypoglycemia and weight control. Numerous AWARD studies have demonstrated the effectiveness of Dulaglutide in lowering blood glucose levels, sustaining weight loss, and diminishing the incidence of hypoglycemia when administered alongside insulin.¹⁰² The fusion protein increases the lifespan of GLP-1 in plasma, prolonging its half-life up to 5 days.⁹ Therefore, it necessitates only a once-weekly subcutaneous injection and requires no dose titration, markedly enhancing patient compliance and rendering it a valuable treatment option for T2DM. Common side effects of Dulaglutide are gastrointestinal reactions, but they can be significantly reduced with prolonged use.^{10–12}

Efpeglenatide

Different from Liraglutide and Dulaglutide, which are commonly used in clinic based on human GLP-1 structure, Efpeglenatide is a long-acting glucagon-like peptide-1 receptor agonist developed by Hanmi based on exendin-4 derived from animal GLP-1. Exendin-4, isolated from the venom of the *Heloderma suspectum*, is a specific and competitive antagonist of GLP-1.¹⁰³ The drug consists of a modified exendin-4 molecule conjugated with a glycosylated IgG4 Fc fragment. Individual amino acid-modified exendin was ligated to IgG4 Fc fragment via a 3.4 kDa mini-Polyethylene Glycol (mini-PEG) linker by long-lasting peptide/protein technology.¹³ The small size of the mini-PEG linker reduces the loss of intrinsic agonist activity. The FC fragment greatly extends the half-life, permitting a prolonged action and pharmacokinetic/pharmacodynamic profile that can reach 5.6 to 7.5 days in patients with T2D.¹⁰⁴ In this way, Efpeglenatide can support flexible dosing frequencies (from weekly, every 2 weeks, and monthly), is well tolerated by patients, and weekly dosing has a significantly more lasting effect on fasting glucose, with much less pharmacokinetic fluctuation following weekly dosing compared to monthly dosing.^{104–106} Efpeglenatide versus liraglutide in the treatment of T2DM, Efpeglenatide is comparable to liraglutide in terms of glucose metabolism and safety.^{13,107} In a phase 3 clinical trial AMPLITUDE-M, once-weekly Efpeglenatide as monotherapy in patients with type 2 diabetes was superior in lowering HbA1c and was able to reduce body weight and fasting glucose compared to placebo.¹⁰⁸ Efpeglenatide, in addition to lowering glucose, significantly reduces several risk factors for cardiovascular and renal disease, such as blood pressure, LDL levels, and albumin/creatinine ratios, resulting in a 27% reduction in the risk of major cardiovascular adverse events and a 32% reduction in the risk of composite renal outcome events.^{109,110} Surprising results suggest that Efpeglenatide can have a controlling effect on blood glucose in pre-diabetic patients, and that it may help to reduce the likelihood of diabetes in high-risk patients.¹¹¹ The most common adverse reactions in all Efpeglenatide are gastrointestinal adverse reactions such as nausea and vomiting.¹³

Basal Insulin Fc

Insulin is a protein hormone secreted by pancreatic β -cells in the pancreas and is the only hormone in the body responsible for reducing blood sugar levels. There are three types of insulin used for therapeutic purposes: animal insulin, human insulin and insulin analogues. Basal Insulin Fc (BIF; insulin efsitora alfa) is an insulin analogue developed by Eli Lilly and Company, with a molecular weight of 64.1 kDa. BIF consists of a fusion of a novel single-chain insulin variant and a human IgG2 Fc domain, having an ultra- long half-life.¹¹² The insulin variant consists of an A-chain analog and a B-chain analog. The B chain is connected to the A chain by a short linker (link1), and the interdomain linker (link2) connects the A chain to Fc.¹⁴ The structure is designed to minimise insulin autoconjugation at locally high concentrations produced by BIF in the homodimeric state and has a prolonged insulin half-life.

Like Icodec, which has entered Phase III clinical trials, BIF is capable of being injected only once a week. In Phase I clinical studies, BIF exhibited a pharmacokinetic half-life of approximately 17 days and maintained its glucose-lowering activity for more than 5 days, perfectly fulfilling the requirement for once-weekly subcutaneous administration. Compared to daily insulin glargine, the ratio of the highest (peak) to lowest (trough) plasma concentrations of the BIF drug was lower (≈ 1.14), suggesting lower between-day glucose variability and more stable glucose reduction.¹¹³ Patients with T2DM previously treated with basal insulin were able to switch to BIF using a loading dose and achieve stable glycemic control.¹¹⁴ In two 26-week trials in patients with T1DM and T2DM respectively, BIF was found to be equally effective as degludec in stabilizing glycemic control on a daily basis.^{115,116} Hypoglycemia was the most common treatment-related adverse effect.¹¹³ Ultra-long-acting fusion proteins, constructed in a similar manner to insulin fusing Fc domain, have also been used in dogs and cats with DM. These proteins can also be administered once a week and have a satisfactory hypoglycemic effect.^{117,118}

Insulin, as the only effective drug for patients with advanced T2DM and T1DM, finally needs to get rid of the inconvenience of daily administration. The weekly insulin being developed will greatly increase patients' compliance. Look forward to phase 3 clinical data (QWINT) of BIF to further determine its effectiveness and safety.

Targeted Anti-Inflammatory Drugs Therapy for Diabetes Mellitus

Etanercept

Tumor necrosis factor- α (TNF- α) is a trimeric protein cytokine that is predominately secreted by macrophages. TNF- α binds to both tumor necrosis factor receptor type 1 (TNFR-1) and type 2 (TNFR-2), exerting a pivotal role in inflammatory activation through multiple signaling pathways.^{119,120} TNF- α was the initial pro-inflammatory cytokine proposed to be associated with the development of insulin resistance.¹²¹ It induces serine phosphorylation of pancreatic IRS-1 through JNK and IKK β pathway, thus decreasing insulin tyrosine kinase activity, impeding insulin-mediated glucose uptake by skeletal muscle and adipocyte, and promoting apoptosis of the pancreas's β cells, thereby aggravating insulin resistance.^{122–124}

Etanercept, an anti-rheumatic drug approved by Pfizer in 1998, is a soluble dimeric fusion protein (TNFRII-IgG1Fc) which formed by fusing the extracellular ligand structural domain of the TNF- α receptor with the Fc segment of IgG1. It competes with TNF- α for linking to the cell surface receptor TNFR, thereby effectively blocking the downward transmission of TNF- α to activate the JNK and IKK β pathways.¹²⁵ Etanercept has a half-life of 3–5.5 days and is usually subcutaneously injected. In a rat model of type 2 diabetes, Etanercept improved insulin and blood glucose levels in rats with type 2 diabetes.¹²⁶ Research has demonstrated that it was not only effective in treating autoimmune diseases in patients, but also significantly improved their insulin resistance.^{127–129} There is also a case study showing that patients with psoriatic arthritis no longer need traditional glucose-lowering medications for poorly controlled T2DM due to Etanercept treatment.¹²⁹ In a small preliminary study treating children with new-onset T1DM, researchers found that treating paediatric patients with Etanercept lowered glycated haemoglobin and increased insulin production, suggesting preservation of beta-cell function.¹⁵ Furthermore, Etanercept can protect the kidneys and improve the progression of diabetic nephropathy by blocking TNF- α -induced cytotoxicity and regulating inflammation.¹³⁰

More research is needed to address the safety and efficacy of Etanercept in T1DM and T2DM. Etanercept maybe is suitable for diabetic patients suffering from chronic autoimmune diseases such as rheumatoid arthritis, etc. It improves concomitant DM by reducing inflammation while fighting immune diseases. The common adverse effects in clinical

practice include infections, painful redness and swelling at the injection site, subcutaneous nodules, and infections from inflammatory response suppression.¹⁶

Abatacept

Cytotoxic T lymphocyte antigen-4 (CTLA-4) is a suppressive immunomodulatory molecule structurally akin to CD28. It binds to B7 molecules but exhibits an expression advantage on Treg, effectively impeding the proliferation and infiltration of effector T cell.^{131–134} The CTLA-4 gene was one of the important susceptibility genes for T1DM, and its expression significantly reduced in T1DM patients.^{135–137}

Abatacept is an immunomodulator that used to treat rheumatoid arthritis. It was marketed by Bristol-Myers Squibb in 2005, which combines the extracellular region of CTLA-4 (CD152) and the IgG1-Fc fragment into a soluble fusion protein through recombinant DNA technology.¹³⁸ Abatacept inhibits T cell activation through binding to the B7 molecule on antigen-presenting cells (APCs) and preventing its interaction with CD28 on T cells.¹³⁹ Additionally, It can also improve diabetic nephropathy by blocking systemic T-cell activation, thus providing prevention and protection.¹⁴⁰

Fujii et al showed that Abatacept, as an immunomodulator, improves insulin resistance in mice by promoting the conversion of adipose tissue macrophages from a pro-inflammatory M1 phenotype to an anti-inflammatory M2 phenotype.¹⁴¹ Ursini et al discovered that Abatacept improves insulin sensitivity in patients suffering from rheumatoid arthritis.^{142,143} Clinical researches have manifested that Abatacept has a significant protective effect on islet β -cells in patients with T1DM. It slows the rate of β -cell function decline and exhibits good tolerability.¹⁴⁴ Abatacept can be administered subcutaneously and has a half-life of approximately 2 weeks. Common adverse events associated with Abatacept include upper airway infections and nausea, with the most serious ones being severe infections and malignant tumors.^{17,18}

sgp130Fc/Olamkicept

Interleukin-6 (IL-6) is a multifunctional inflammatory factor that triggers intracellular signaling by binding specifically to the interleukin-6 receptor (IL-6R), activating the JAK/STAT and ras/MAP kinase pathways.^{145,146} IL-6 conjugates with IL-6R through two distinct signaling pathways: (1) the classical signaling pathway, which protects cellular tissue and has anti-inflammatory effects by binding to membrane-associated IL-6R, stimulating intestinal regeneration, inhibiting epithelial cell apoptosis, reducing bacterial infection and inducing acute temporal responses in the liver, and potentially beneficial for glucose metabolism.^{147,148} (2) Trans signaling pathway, which exerts pro-inflammatory effects by binding with sIL-6R, recruiting monocytes, inhibiting T cell apoptosis, and suppressing differentiation of regulatory T cells.¹⁴⁷ A significant dose-response correlation exists between IL-6 levels and the risk of T2DM.¹⁴⁹ Furthermore, elevated circulating IL-6 levels are a predictor factor of T2DM. IL-6 can be combined with sIL-6R and gp130 to exert pro-inflammatory effects through the JAK/STAT/SOCS3 pathway or JAK/JNK pathway, affecting IRS phosphorylation and inducing insulin resistance.¹⁵⁰

Stefan Rose-John et al constructed a fusion protein known as sgp130Fc/Olamkicept, created by combining the extracellular part of dissoluble glycoprotein 130 (gp130) to the IgG1-Fc fragment.¹⁵¹ This fusion protein is suitable for intravenous medication and has a half-life of 4.7 days. Additionally, it selectively inhibits the IL-6 trans-signaling pathway. The sgp130Fc exclusively inhibits IL-6 trans-transduction by binding to sIL-6R without affecting classical IL-6 signaling. Therefore, the sgp130 prevents the pro-inflammatory effects while preserving IL-6 anti-inflammatory and auto-stabilizing abilities, thus avoiding severe immunosuppression and fatal infections. A recent in vitro study showed that sgp130Fc significantly reduced oxidative stress in mouse retinal endothelial cells, thereby resisting persistent hyperglycemia that leads to increased ocular retinal oxidative stress and inflammation, and delaying the progression of diabetes mellitus.¹⁵² Atherosclerotic cardiovascular disease (ASCVD) is a prevalent macro-vascular diabetic complication. sgp130Fc is currently poised to enter phase 2 clinical studies in ASCVD with previous results indicating favorable patient tolerability.^{153–155} In a mouse model of atherosclerosis, sgp130Fc showed vast atherosclerotic plaque degradation and vessel wall inflammation with few side effects in high-risk ASCVD patients.^{155,156} sgp130Fc, as the sole available anti-inflammatory protein that specifically blocks IL-6 transduction signaling, it may be more effective in the treatment of T2DM combined with other diabetes drugs in new treatment strategies.

Alefacept

Alefacept, a fusion protein developed by Biogen Inc. for the treatment of psoriasis, consists of two extracellular regions of lymphocyte function-associated antigen 3 (LFA-3) conjugated to an IgG1 Fc.²⁰ By binding to IgG1 Fc, Alefacept has an extended half-life of 12 days and is used as a once-weekly dosage in T1DM therapy. LFA-3 is primarily found in antigen-presenting cells (APCs) and serves as a ligand for lymphocyte function-associated antigen-2 (CD2). CD2 is a surface protein expressed on the majority of human T-cells, with particularly high expression on effector-memory T (Tem) cells. As mentioned above, the pathogenesis of T1DM is directly related to the destruction of β -cells by effector T-cells.¹⁵⁷ Alefacept, as a blocker of LFA-3/CD2 interaction, specifically binds to CD2 and inhibits the interaction of CD2 with the ligand LFA-3, thus blocking the co-stimulation of T-cells by APCs and depleting effector-memory T-cells to ultimately reduce the destruction of β -cells.^{21,158,159}

In a Phase 2 clinical trial enrolling 49 subjects with new-onset T1DM (within 100 days of diagnosis), investigators evaluated the treatment difference of once-weekly Alefacept compared to placebo.²¹ C-peptide responses were significantly preserved with Alefacept compared to placebo at 1 and 2 years.¹⁶⁰ Levels of C-peptide secretion are significantly associated with glycemic control, glycemic variability and partial clinical remission. At 24 months, the exogenous insulin requirements were lower and the incidence of major hypoglycemic events was reduced by approximately 50% in patients who received Alefacept injections. Alefacept's immunological intervention in T1DM reduced insulin requirements and major hypoglycemic events in new-onset T1DM. What's more, it also preserved residual beta-cell function in patients with newly diagnosed T1DM. Alefacept has a good safety profile, with the major adverse events being hypoglycemia and infection.

There is a lack of research on the use of Alefacept in T1DM at this stage, and it would be valuable to investigate alternative treatments by administering additional courses of Alefacept at higher dosages.

Others

The following two drugs have not been thoroughly researched for their effectiveness in treating diabetes, therefore, only their structures will be briefly mentioned.

The inflammatory factor IL-1 β reduces insulin secretion and improves insulin resistance.¹⁶¹

Conversely, IL-1 receptor antagonists improve insulin secretion from β cells and reduce systemic inflammatory marker expression.¹⁶² Rilonacept, an IL-1 receptor antagonist marketed in 2008, is a long-acting dimeric fusion protein that fuses extracellular portion of IL-1 receptor 1 (IL-1R1) and IL-1 receptor accessory protein (IL-1RAcP) with the Fc portion of IgG1. Rilonacept binds both IL-1 α and IL-1 β , thereby antagonising their binding to the IL-1 receptor. It has a half-life of 6–8 days.^{163,164} A Phase 1 trial of Rilonacept in patients with T1DM showed that Rilonacept was well tolerated in patients with newly diagnosed T1DM, with adverse effects mainly being injection spot reactions, cardiopulmonary infections, upper airway infections and mild neurological symptoms.²²

Furthermore, a novel insulin sensitizer named YIMINSU has been developed by utilizing the structure of the hydroxyl terminal in the extracellular domain of the insulin receptor, a polyglycine sequence and Fc fragment of human immunoglobulin IgG4 (INBP-PolyG-IgG4Fc). It can improve insulin resistance by activating the AMPK/PI3K/AKT signaling pathway to initiate downstream cascade signals.^{165,166}

Summary

The Fc fusion protein, as a derivative field of antibody application, has a wide range of prospective applications due to its unique characteristics. Although IgG Fc fusion protein has a longer half-life and less rejection in humans compared to other traditional hypoglycemic segments, they are not suitable for oral administration or the treatment of T1DM, and currently cannot be recommended as a first-line hypoglycemic agent. We anticipate that structural optimization of Fc fragments and regulation of FcRn-IgG interactions will be of attention in the near future.⁵¹

Currently, there exists a smaller IgG fragment called the 27 kDa Monomeric IgG1 Fc (MFC), which is smaller than the Fc fragment. This MFC fragment exhibits faster diffusion than the common Fc fragment, leading to quicker attainment of blood concentrations and a faster onset of action. Moreover, MFC remains unaffected upon binding and

possesses a considerably longer half-life, allowing it to achieve the same effect as the Fc fragment.^{167,168} MFc binds closely with FcγRI, without any direct cytotoxicity and even safer than the Fc fragments of IgG2 and IgG4. It is expected to play a significant role in the treatment of chronic inflammatory diseases and solid tumors as an incipient drug-delivery protein. The selection of appropriate IgG fragments as fusion carriers, along with sequence modification, PEGylation, and glycosylation modification of Fc fragments, can prolong the plasma half-life of fusion proteins and optimize their structures and functions, ultimately achieving optimal therapeutic effects.

Albumin-Like Fusion Protein-Based Drugs

The Overview of Albumin and Its Fusion Protein-Based Drugs

Human serum albumin (HSA) is the most abundant protein in plasma, with a molecular weight of approximately 66.5 kDa. It avoids being quickly degraded through a pH-dependent recirculation mechanism mediated by FcRn, resulting in a half-life of 19 days. HSA is a heart-like molecule that contains three homologous structural domains (DI, DII and DIII). DI and DIII are implicated in the interaction of albumin and FcRn, with DIII playing a key role in binding.^{169,170} The differences between FcRn-IgG Fc and FcRn-albumin are as follows: (i) albumin-binding site is located on the opposite side of the IgG-binding site, and albumin binds to FcRn in a 1:1 manner;^{169,171} (ii) albumin does not bind to the classical FcγR, thereby avoiding the immunomodulatory effects and cytotoxic responses induced by the Fc segment, which reduce the risk of unwanted immune activation. Albumin is used as a medication vector due to its minimal immunogenicity, highly bio-compatibility, and lowly toxicity.¹⁷² Similar to Fc fusion proteins, albumin has a wide range of fusion targets which increases the bioavailability and half-life of the target protein.¹⁷³

Albumin fusion protein-based drugs are a novel type of recombinant protein drugs produced by genetically fusing the structural domain of albumin to a functional protein possessing specific biological activity. There are usually two types of albumin used for functional protein fusion: HSA and recombinant human serum albumin (RHSA). HSA is obtained through isolating and purifying blood donor plasma, but carries the risk of virus or prion contamination. Conversely, RHSA is produced via the secretion of the target protein using a yeast expression system, followed by purification to eliminate any contaminants derived from yeast.^{174–176} It has also been reported that cost-effective rice seeds can also successfully express RHSA.^{177,178} Albumin fusion proteins have a long drug half-life, high histocompatibility, and offer diverse ligand binding sites which can improve drug delivery and reinforce pharmacokinetic performance.

Albiglutide

Albiglutide, a GLP-1RA, was the first albumin fusion protein drug ratified by FDA in 2014. Albiglutide is constructed by fusing two tandem copies of anti-DPP-IV hydrolyzed GLP-1 analogue to the N-terminus of albumin.^{179,180} The main reason for the extended half-life of albiglutide (6–8 days) and the need for only one weekly subcutaneous injection is the replacement of the DPP-IV hydrolysis site from alanine to glutamate and its conjugation to a high molecular weight protein.

In contrast to other GLP-1RAs such as Exenatide and Liraglutide, Albiglutide not only effectively controls blood glucose concentrations and mean glycated hemoglobin levels, but also exhibits a lower likelihood of gastrointestinal adverse effects. Furthermore, it has a remarkable advantage in reducing major cardiovascular adverse effects, including atherothrombosis and myocardial infarction.^{23,24,179,181–185} The combined effect of Albiglutide, compared to a placebo, was a 22% reduction in the risk of major cardiovascular disease related deaths. Additionally, Albiglutide exhibits good tolerability in T2DM patients with mild, moderate or severe renal insufficiency. It did not require dose adjustments for renal impairment, significantly reduces HbA1c expression in combined drugs, and is better tolerated by the stomach and intestines.^{186,187}

Albulin

Albulin is a long-acting insulin analogue. It is a recombinant fusion protein consisting of the A and B chains of insulin connected by a dodecapeptide junction and attached to the amino terminus structural domain of natural HSA. In vitro studies have shown that, except for a low affinity for insulin-related receptors, Albulin functions similarly to insulin, especially when it inhibits gluconeogenesis in hepatocytes and stimulates glucose uptake by adipocytes.²⁵ Experimental

data indicate that the terminal half-life of albumin in normoglycemic mice is 7 hours, while the anticipated elimination half-life of albumin in a 70 kg man is approximately 50 hours.²⁶

Summary of Albumin-Like Fusion Protein-Based Drugs

Albumin, as a large molecular protein, exhibits good bio-compatibility and possesses long half-life in drug fusion. However, attaching bulky proteins to fusion targets will inevitably affect the biological activity of fusion targets. Although higher doses of fusion proteins in treatment may compensate for the loss of efficacy, they also significantly increase the incidence of adverse effects. Recent studies have found that the fusion of high-affinity structural domain (ABD) of HSA with GLP-1 protein can maintain the natural bioactivity of GLP-1 and increase its half-life by 1000-fold. This finding offers promising prospects for the development of T2DM treatment.¹⁸⁸

Transferrin-Like Fusion Protein-Based Drugs

Overview of Transferrin

Human transferrin (HTF), a novel efficient carrier with a molecular weight of 78 kDa, is mainly synthesized in the liver. Transferrin has two types of receptors: TFR1 and TFR2. TFR1 is predominantly located on the surface of somatic cells and facilitates the TF cellular uptake, it is associated with the production of mature erythrocytes. TFR2 is primarily expressed in hepatocytes and erythroid precursor cells, it is associated with the maintenance of iron levels in the body. Through the TF/TFR1 system, transferrin can increase the half-life in serum to 8 days.^{53,189}

The HTF fusion protein combines the structural domain of transferrin with the target peptide to form a hybrid molecule through genetic engineering techniques, giving the stable properties of transferrin to the peptide. Transferrin, as a drug delivery system, can deliver drugs in various forms.⁵⁴ HTF has the following advantages on treating diabetes mellitus:

1. It has the ability to regulate insulin resistance.¹⁹⁰ Iron homeostasis is essential for maintaining the normal pancreatic β -cell function and glucose metabolism. Iron overload in the body can induce iron death through increasing oxidative stress, lipid peroxide production, and free radical level. Furthermore, It disrupts insulin signaling pathways and impairs autophagy, resulting in pancreatic cell death and insulin resistance. Consequently, this leads to hyperglycemia and elevated serum iron levels, aggravating the insulin resistance.^{191–193} In diabetic patients, intravenous apolipoprotein-transferrin (apo-TF) can reduce the level of free iron, mitigate oxidative damage, postpone the insulin resistance, and decrease the incidence of cardiovascular disease¹⁹⁴.
2. It possesses the capability to traverse the blood-brain barrier.^{195,196} TFR1 exhibits extensive distribution within the blood-brain barrier, and the transport of substances mediated by the transferrin receptor has emerged as a prominent therapeutic target in the central nervous system with neurodegenerative disease treatment potentials.
3. Administered orally in medication.^{55,197} HTF directs the absorption and transportation of drugs through the rich TFR in intestinal epithelial cells,¹⁹⁸ Additionally, HTF possesses robust anti-protease hydrolysis capabilities, rendering it an efficient carrier for oral proteins and peptide-based therapeutic agents intended for systemic treatment. It can effectively prolong the efficacy of GLP-1 by linking with GLP-1.¹⁹⁹
4. Providing recombinant production systems with high efficiency and lower prices.²⁰⁰ Cheap and reliable edible genetically modified tobacco systems can produce therapeutic proteins and bioactive peptides for direct oral administration.
5. The utilization of affordable, edible genetically modified (GM) tobacco as a primary resource eliminates the need for protein purification and processing Hence, the costs of production are greatly reduced compared to traditional yeast or animal cell cultures.

ProINS-TF

ProINS-TF is a novel long-acting liver-targeted insulin precursor drug composed of the C-terminal of human proinsulin (ProINS) fused with the N-terminal of human serum TF.²⁰¹ The TF-TFR endocytic circulating pathway facilitates the

conversion and release of proinsulin-transferrin (ProINS-TF) in the immuno-reactive insulin-transferrin (irINS-TF), the active form with a relative molecular mass of 88.1 kDa and a clearance half-life of 7.29 h.²⁷ In streptozotocin-induced T1DM mice, ProINS-TF showed a hypoglycemic effect for up to 40h.²⁰² ProINS is an insulin precursor, and under physiological conditions in which blood proinsulin levels are low, its function similarly to insulin except for hepatic specificity. Pharmacokinetic researches have shown that ProINS has a longer distribution and elimination half-life compared to insulin. However, the conversion of ProINS to insulin *in vivo* is notably inefficient. ProINS needs to be increased more than tenfold to achieve the equivalent hypoglycemic pharmacological effect. Despite this dosage escalation, the biological utilization of ProINS remains at less than one percent compared to insulin.^{203–206}

By combining ProINS with HTF, its elimination half-life is extended from 0.5 h to 7.29 h, with a sustained hypoglycemic effect of at least 12 h.²⁷ ProINS-TF has a high liver targeting specificity.²⁰⁷ Studies have shown that TFR-mediated endocytosis in the liver can activate ProINS-TF into irINS-TF to phosphorylate Akt, which plays a role in regulating blood glucose.^{201,208}

irINS-TF effectively resolved the slow onset of ProINS-TF, further improved the binding affinity and prolonged the activation time of IR, and could achieve the same or even better sustained glucose-lowering effect compared to natural insulin in the treatment of T2DM. Utilizing the transgenic rice expression system, it is possible to produce ProINS-TF with high activity and oral administration at a low cost and a large scale, which provides a material guarantee for future research.¹⁹⁷

Numerous prior studies have explored for transferrin fusion proteins on the perspective of receptor-ligand binding specificity or targeted delivery,^{209,210} however, few studies have been dedicated to the extension of targeting half-life, let alone the study of fusion transferrin hypoglycemic agents. The successful construction of ProINS-TF provides a promising avenue for the future development of long-acting hypoglycemic drugs.

Conclusion

Using molecular biology techniques to integrate therapeutic protein or peptide sequences into transporter proteins with long half-lives, such as Fc fragment, albumin and transferrin, can extend the duration of short-acting functional substances such as GLP-1 and ProINS. This process effectively mitigates insulin resistance and regulates blood glucose, providing a reference for the development of new long-acting diabetes drugs.

From a therapeutic perspective, protein therapies may be safer than gene therapies because they do not involve random or permanent genetic alterations.

In contrast to protein and peptide drugs which require frequent long-term subcutaneous injections, fusion protein-based drug therapies are unique in the following prospects: on the one hand, fusion drugs based on natural transporter proteins require less frequently administration. On the other hand, transferrin fusion proteins are produced by plant expression systems, resulting in cost-effectiveness and oral properties. This dual advantage enables more convenient, manageable, and patient-compliant treatment options.

It should be noted that linking bulky proteins to fusion targets will inevitably impacts the biological activity of the fusion target, which poses serious challenges for drug formulations and increases the occurrence of side effects.

In the construction of drug molecules, more attention should be paid to the manner in which the fusion protein binds to the target protein, the specific type and length of the linker, etc., avoiding damage the target protein activity.^{211,212} A fusion protein characterized by stable properties and favorable biological behavior holds substantial market potential, yet its development still presents formidable challenges.²¹³

Diabetes mellitus is a global disease that can cause complications in multiple organs. It disrupts the metabolism of carbohydrates, proteins, and fats, negatively impacting both physical and mental health. Despite the availability of numerous drugs for the treatment of diabetes mellitus, there remains a dearth of fusion protein-based hypoglycemic drugs in development.

This review focuses on fusion protein-based drugs designed to prolong the half-life of functional proteins, including Fc fusion protein, albumin fusion protein, and transferrin fusion protein.

Nevertheless, some of the drugs mentioned have not been tested in clinical trials. Hence, their effects and adverse effects need to be further studied. In addition, protein-based drugs possess immunogenicity. And despite the high homology of fusion proteins, the possibility of immune reactions in allergic patients cannot be disregarded. It is

anticipated that with the rapid development of bio-pharmaceutical technology, fusion protein-based drugs will have a bright future in the prevention and treatment of diabetes mellitus.

Diabetes, Metabolic Syndrome and Obesity

Dovepress

Publish your work in this journal

Diabetes, Metabolic Syndrome and Obesity is an international, peer-reviewed open-access journal committed to the rapid publication of the latest laboratory and clinical findings in the fields of diabetes, metabolic syndrome and obesity research. Original research, review, case reports, hypothesis formation, expert opinion and commentaries are all considered for publication. The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.

Submit your manuscript here: <https://www.dovepress.com/diabetes-metabolic-syndrome-and-obesity-journal>
