Abstract: The introduction of the Duke criteria and transesophageal echocardiography has improved early recognition of infective endocarditis but patients are still at high risk for severe morbidity or death. Whether an exclusively antibiotic regimen is superior to surgical intervention is subject to ongoing debate. Current guidelines indicate when surgery is the preferred treatment, but decisions are often based on physician preferences. Surgery has shown to decrease the risk of short-term mortality in patients who present with specific symptoms or microorganisms; nevertheless even then it often remains unclear when surgery should be performed. In this review we i) systematically reviewed the current literature comparing medical to surgical therapy to evaluate if surgery is the preferred option, ii) performed a meta-analysis of studies reporting propensity matched analyses, and iii), briefly summarized the current indications for surgery.

Keywords: endocarditis, surgery, antibiotics, review, meta-analysis, propensity analysis, mortality, complications

Introduction

Over the last decades infective endocarditis (IE) has been described extensively.¹ This has identified risk factors, clinical features, and predictors of outcome, which led to the prescription of antibiotic prophylaxis during the perioperative stage of dental and cardiovascular surgery.^{2,3} Furthermore, the development of the Duke criteria as a diagnostic tool⁴ and the use of transesophageal echocardiography (TEE) have contributed significantly to early recognition. Despite these developments, outcomes nonetheless remain unsatisfactory.⁵⁻⁷ Peripheral or cerebrovascular embolisms and acute heart failure can cause a drastic decrease of the quality of life. Moreover, mortality rates continue to be as high as 50% in some studies.

The usage of an antibiotic regimen alone or in combination with surgical intervention is an ongoing debate. Studies investigating the best treatment have shown that surgery in combination with antibiotics is superior in some indications.⁸ The decision whether and when to treat endocarditis surgically often depends on local practice. Uniform recommendations are therefore difficult to make and an overall superiority of medical or surgical treatment is not yet established. In a propensity matched analysis, surgery seemed to be superior regarding in-hospital mortality,^{9,10} but at long-term follow-up, data suggests no benefit of surgical therapy compared to an exclusively medical regimen.^{11,12} A better outcome with surgical therapy was recently demonstrated in the largest reported matched cohorts.¹³ Still, these studies with propensity matched analysis do not produce unambiguous results.¹⁴

Timing of surgery is important. This issue has been extensively addressed and there is substantial evidence that early surgery can be performed safely, but no consensus exists on the optimal timing of valve replacement in the active phase of endocarditis.^{15,16} Waiting increases the risk of stroke or peripheral emboli while early surgery increases the risk of procedure-related complications, and longer antibiotic treatment can potentially avoid valve replacement.

It is clear that the optimal treatment for IE remains challenging. The ongoing ENDOVAL trial will be the first to report results of patients treated medically or surgically in a randomized fashion and can provide important data.¹⁷ Before these results will be presented treatment preferences are based on current data. This review systematically evaluates studies comparing medical to surgical therapy and discusses the timing of surgery.

Current data

Systematic review: medical or surgical therapy?

We performed a systematic review of studies reporting hospital mortality after medical and surgical treatment separately. The Medline database, web-of-science, and The Cochrane Library were consulted with search entries of “endocarditis” and “treatment or therapy or surgery or medical” and “outcome or survival or mortality or hazard ratio” in all possible combinations. Studies were excluded if they focused on a specific aspect of endocarditis, reported results of an exclusive patient cohort, or included less than 50 patients. Multiple studies overlapped in patient populations; only the study with the largest number of patients was included.

Forty eligible studies were identified.^{9–13,18–52} Data was pooled to obtain an overall view of the studied population; a total of 11,348 IE episodes were analyzed (Table 1, Figure 1). The largest study on endocarditis to date is from the International Collaboration on Endocarditis-Prospective Cohort Study (ICE-PCS), which was a prospective, multicenter, international registry with 2,781 patients from over 50 centers.⁵³ The combined data from the 40 studies had similar baseline characteristics for gender, PVE (%), and periannular abscess (%). Vegetations were visualized less in the combined data (87% compared to 70% in our data). The cause of endocarditis was also similar, although the number of *Staphylococcus aureus* infections was 21% in the combined series as to 31% in the registry, and viridans streptococci was identified in 20% compared to 17% in the ICE-PCS registry.

Table 1 Characteristics and outcome of IE in pooled analysis of 40 systematically included studies

	Episodes (N = 11,348) (%)	Number of studies (N)
Characteristics		
Definite infective endocarditis according to Duke criteria	95.4%	(33)
Males	65.5%	(39)
Prosthetic valve endocarditis (all studies)	20.2%	(39)
Prosthetic valve endocarditis (natural)	21.9%	(28)
Surgery	41.5%	(40)
Echocardiographic findings		
Vegetations	69.4%	(32)
Mobile vegetations	51.7%	(7)
New valve regurgitation	47.6%	(7)
Periannular complications	16.2%	(4)
Abscess	12.7%	(16)
Perforation	10.4%	(8)
Prosthetic valve dehiscence	6.9%	(12)
Indications for surgery		
Heart failure	49.7%	(17)
Emboli	17.8%	(16)
Persistent infection	18.8%	(14)
Abscess	17.4%	(12)
Large vegetation	21.5%	(6)
Complications		
Emboli		
Brain	14.9%	(14)
Systemic/peripheral	21.2%	(21)
Unspecified	33.0%	(9)
Heart failure	34.1%	(34)
Neurological events	24.0%	(7)
Stroke	16.3%	(6)
In-hospital mortality	19.2%	(40)
Surgical treatment	15.8%	(40)
Medical treatment	20.3%	(40)

Notes: Prosthetic valve endocarditis “all studies” shows the incidence in all episodes. The “natural” occurrence of prosthetic valve endocarditis is the percentage in studies including all cases of endocarditis, and not studies specifically including prosthetic or native valve cases.

Results were remarkably similar; occurrences of stroke and non-stroke embolism were almost identical. Furthermore, heart failure was diagnosed in 34% compared to 32% in ICE-PCS, and in-hospital mortality was 19% versus 18% respectively.

One limitation of the ICE-PCS registry is that the indications for surgery were not reported. In our combined data of the 40 studies, surgery was performed in 4,714 episodes of endocarditis. Seventeen studies reported indications for surgery; heart failure (49.7%) was the main reason, others were large vegetation on echocardiography (21.5%), persistent infection (18.8%), embolic complication (17.8%), or abscess formation (17.4%). Although it is likely that more complex

Figure 1 Causative microorganisms from pooled data of 11,348 IE episodes.

cases of endocarditis underwent surgery, the in-hospital mortality was significantly lower in these patients compared to those medically treated (15.8% versus 20.3%). This could be explained by the fact that patients deemed too high risk for surgery due to their condition were treated non-surgically, thereby increasing the observed mortality in the medically treated patient cohort. As a result of treatment preferences, most studies include significant treatment bias and robust evidence-based conclusions are unavailable. Predicting which treatment is most beneficial for the individual patient remains challenging.

Meta-analysis: propensity score studies

A number of studies used propensity matching to compare medical to surgical therapy (Table 2).^{9–14,54} Studies that report in-hospital mortality either show results favoring surgical therapy over medical therapy or no statistical difference (Table 2). Combined data reveal an overall odds ratio of 0.47 (95% confidence interval [CI] 0.38–0.58) supporting surgery. There is however a marked statistically significant heterogeneity ($I^2 = 65\%$, $P = 0.005$ (Figure 2)), meaning that there is excessive variation in the results.

Bias

Even though both the pooled and meta-analysis limit bias to some extent, included studies that report results after IE treatment are inherent to treatment and referral bias.

First of all, studies comparing medical to surgical treatment in a randomized fashion are not yet available. Baseline characteristics are therefore incomparable between groups. Even with propensity matched analyses, patients can only be matched considering the collected variables. Characteristics such as frailty are not available but can influence outcome. Other certain endocarditis-specific variables warrant surgical intervention and these variables will not be available in the medical group. These

Table 2 Studies reporting propensity matched analysis

First author, year	Follow-up	Total no. of patients (N)	Matched no. of patients (N)	Mean age (years)	Prosthetic valve endocarditis (%)	Mortality surgical (%)	Mortality medical (%)	Hazard ratio/odd ratio surgery (95% CI)

Notes: Multiple values in one entry are listed as 'surgical patients : medical patients'. *Study in which 5 groups were matched based on the likelihood of undergoing surgery.

Figure 2 Meta-analysis of studies with propensity analysis.

variables can therefore not be matched, and while groups are allegedly ‘matched’, they often are not completely. A recent study demonstrated that adjustment for an additional *survivor bias* factor is needed, as it can significantly alter the results.⁵⁵

Referral bias embodies another bias that is often present in the included studies. Patients from the ICE-PCS registry transferred to tertiary care centers more frequently underwent surgery and had higher rates of complications such as stroke, heart failure, or valve regurgitation.⁵⁶ Results from certain centers can therefore be skewed in relation to other outcomes, and this should be kept in mind when evaluating these studies.

The studies included in the meta-analysis have previously been shown to be incomparable on multiple fronts. Inconsistent results are therefore likely to be not only dependable of the given treatment, but also due to used methods of data acquirement, co-morbidity definitions, the number of variables matched for, reporting of data, and statistical methods.⁵⁷ Furthermore, the deliberate decision whether to treat medically or surgically is based on certain specific characteristics of the patient, and no study without or with propensity analysis can adjust for clinical judgment.

Indications and timing for surgery

In the pooled data, surgery was performed in 41.5% of IE cases. Apart from studies comparing medical to surgical therapy, extensive results of surgical series have been described. These studies have furthermore provided data on surgical indications and many of these indications have now been included in current guidelines.^{3,58,59}

Congestive heart failure

Infective endocarditis often causes heart failure as a result of valve regurgitation, or sometimes because of valve obstruction or prosthetic valve dehiscence. Heart failure is a prognostic factor of impaired survival, independent of the causative microorganism or the status of infection. Many surgeons consider it as the main indication to perform surgery.⁶⁰

The timing of surgery depends on the progression of heart failure. Urgent surgery is needed if acute regurgitation of the aortic valve is present. A slower progressive presentation gives the opportunity to postpone surgery and await the effect of medical therapy.

Periannular extension

In native valve endocarditis periannular extension is present in 10%–40%, but in prosthetic valve endocarditis (PVE) this is as high as 56%–100%.⁶¹ Annulus involvement is associated with development of heart failure and increases mortality. Surgery is often indicated, especially when an abscess is present. The pooled data (Table 1) suggests that this is the case in almost 13%, but a recent study focusing exclusively on surgical patients showed a rate of 38%.⁶² Medical therapy is insufficient if an abscess has been detected on TEE, and guidelines therefore suggest that these patients should undergo surgery.³ If early surgical intervention is not performed an abscess can progress into fistulous cavities resulting in a mortality rate as high as 41%.⁶³

Periannular extension is likely in case of persistent infection despite antibiotic therapy and surgery should be considered. An advantage of surgery over an antibiotic

regimen is expressed in the completeness of therapy. Open-heart surgery provides the opportunity to extensively remove infected tissue to prevent relapses.

Emboli

One of the major complications of IE is the development of systemic emboli in 22%–50% of the patients.^{64,65} Common affected sites are the lungs, spleen and peripheral arteries, but the most affected (65%) is the central nervous system (CNS).⁶⁵ Not only morbidity is high, but CNS emboli significantly increase the risk of mortality.

The prevention of such events is difficult, since the event itself can be the initial presentation of IE. These patients have a clear indication for urgent surgery. This however carries an increased risk of intracranial hemorrhage while waiting and medical therapy increases the risk of recurrent emboli. Current recommendations therefore suggest a 2–4 week antibiotic regimen before surgery can be performed safely. In patients who present with transient ischemic attacks or “silent” emboli early surgery appears safe. No prospective studies have confirmed these findings, and more data is needed.⁶⁶

Large vegetations on TEE are often of prognostic value of embolic events. Although there is not a uniform cut-off value, vegetations between 10–15 mm are an indication to perform urgent surgery.

Persistent sepsis

An ongoing infection despite antibiotic therapy is common with aggressive microorganisms, abscess formation, or large vegetations. Patients with persistent sepsis are at high risk to develop multi-organ failure and guidelines indicate that surgery is needed in these patients if cultures persist to be positive after 7 days of medical therapy.^{59,62} Some caution is however advised in patients that develop recurrent fever after an initially good response to antibiotics, because the fever could be explained by other reasons than the endocarditic valve. Surgery is only indicated if further diagnostics confirm persistent infection of the valve.⁶¹

Microorganism

A fungal cause often marks a complex case of IE. First of all, the diagnosis is delayed due to recurring negative blood cultures. Once IE is established medical therapy with antifungals is frequently unsatisfactory, resulting in the need for surgery in a large percentage of patients. Other indications for surgery are large vegetations and periannular extension that regularly complicate fungal IE.

Endocarditis caused by bacteria can be challenging as well, especially *Staphylococcus aureus*.⁶⁷ These complicated infections with large vegetations and embolic manifestations result in an increased risk of mortality. If multi-resistant *S aureus* is detected, surgery is the only conclusive therapy and is always indicated.

Several other micro-organisms such as *Brucella*, Q fever, *Pseudomonas aeruginosa*, and *Staphylococcus lugdunensis* indicate surgical intervention, but are rare in presentation.^{68–71}

Prosthetic Valve Endocarditis (PVE)

In approximately 20% of IE a prosthetic valve is involved.⁷² A distinction is often made between early and late cases based on the time of diagnosis after initial surgery. The prognosis of PVE is worse than in native valve IE.⁷² Several studies have compared outcomes after medical and surgical therapy in PVE.^{14,22,25,33,38,51} A large cohort study of 367 prospectively followed patients showed that in-hospital mortality rates were similar: 23.4% in medical and 25% in surgical patients.¹⁴ Six months survival in a different study also showed no favorable result for surgery in 80 patients (70% survival in medical and 73% in surgical patients).⁷³ Surgery for PVE is often indicated, but is a troublesome procedure which is reflected in a high recurrent IE rate of up to 15%.^{74,75}

Right-sided endocarditis

The incidence of right-sided IE represents less than 10% of all cases of IE.^{76,77} Right-sided endocarditis mainly occurs in patients with intravenous drug use, pacemaker or central venous lines, or congenital heart disease. The majority of cases involve the tricuspid valve, while isolated pulmonary valve endocarditis is rare.⁷⁸

Isolated right-sided endocarditis has a favorable prognosis with low in-hospital mortality and the primary approach in these patients should therefore be conservative. Most cases respond to medical therapy and surgery is only necessary in a small minority of patients.⁷⁹

The 10 and 20 year survival rate after surgery for isolated right-sided endocarditis has been reported to be 70% and 58% respectively, which is better than patients with left-sided IE.⁸⁰

Device-related endocarditis

The use of pacemakers, defibrillators, and other implants has grown significantly over the last decades. As a result, endocarditis is more frequently associated with these devices.⁸¹

These types of endocarditis require excision of the infected device and complete eradication of the infection. Only thereafter can a new device be implanted. Percutaneous techniques allow the cardiologist to perform this procedure, and surgeon involvement is therefore not necessary.

Risk stratification

Due to the variability in the complexity of IE, the prognosis strongly depends on the individual patients' characteristics. Some patients benefit more from surgery than others, and to identify in which group of patients surgery can be performed safely and with an adequate result, a recent study developed a simplified risk scoring system including 13 variables.⁸² Although this model is noteworthy, one should be reminded that data is from the Society of Thoracic Surgeons (STS) database in which >19,000 patients surgically treated for IE were analyzed to relate baseline characteristics to 30-day outcomes. The database only includes general characteristics, but endocarditis-specific variables such as vegetation size, prosthetic valve endocarditis, or periannular extension are lacking. The model therefore is similar to the STS score, and is not specific for endocarditis. Also, this score is only based on surgical patients, and therefore it cannot be used to identify those who would benefit most.

Another recent study showed that additive and logarithmic EuroSCORE have a predictive value of 0.84 and 0.85 respectively, confirming that available risk models not specific for endocarditis can be sufficient to predict mortality.⁷⁷

Transcatheter aortic valve endocarditis

The introduction of transcatheter aortic valve implantation (TAVI) to treat severe aortic stenosis could change the face of PVE. The occurrence of early PVE could be influenced by the difference between a sternotomy and access through the groin. The increased prevalence of paravalvular leakage raises concerns because of the associated risk of endocarditis. Little is known about the true incidence of endocarditis after TAVI; to date it has only been anecdotally described.^{83,84} Follow-up has been short, and late PVE has therefore not yet been fully addressed. TAVI has recently shown positive results in the PARTNER (Placement of Aortic Transcatheter Valves) trial,⁸⁵ and more randomized trials will start enrollment soon to broaden the indication to lower risk patients.⁸⁶ Further data will contribute to the unknown prevalence of endocarditis after TAVI.

New insights

Late in 2011 the first randomized data from the ENDOVAL trial on surgical or medical treatment for IE will be available. The trial will only include high-risk patients with 1) periannular complications, 2) new onset aortic-ventricular block, 3) new onset severe valve regurgitation, 4) early-onset PVE, or 5) *Staphylococcus aureus* endocarditis. The trial will likely lead to treatment preferences for most endocarditis patients. Too high-risk patients with an EuroSCORE > 40% or an emergent/urgent indication for surgery because of heart failure due to valvular insufficiency, fungal endocarditis, or septic shock are excluded.¹⁷ It is these patients that lead treatment bias when comparing studies from different centers. Some surgeons are willing to operate on the very high-risk patients, while others are reticent. To evaluate the need for surgery in high risk patients, another trial in high-risk patients is preferable. The ENDOVAL trial is the first trial assessing the use of early surgery in endocarditis, and could stimulate others to follow.

Conclusions

Endocarditis has been extensively described over the last decades and treatment with surgery is established for certain indications associated with improved survival. Surgical treatment of PVE carries quite a high mortality and requires close follow-up due to a continued postoperative risk. The selection of patients who benefit most from valve replacement is becoming more transparent, but treatment often remains biased because of surgeon preferences. A large number of ongoing studies and randomized trials will produce stronger evidence.

Vascular Health and Risk Management

Publish your work in this journal

Vascular Health and Risk Management is an international, peer-reviewed journal of therapeutics and risk management, focusing on concise rapid reporting of clinical studies on the processes involved in the maintenance of vascular health; the monitoring, prevention and treatment of vascular disease and its sequelae; and the involvement of

metabolic disorders, particularly diabetes. This journal is indexed on PubMed Central and MedLine. The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.
